

Figure 1 Lognormal distribution of circuit breaker generic failure rates

Environment z score $+0.5$ – (exposed marine location).

On the basis of these z scores, estimated design, operation, and environment k factors are as follows:

$$k_1 = e^{0.25} = 1.3$$

$$k_2 = e^0 = 1.0$$

$$k_3 = e^{0.5} = 1.6$$

Therefore, Πk_i is approximately 2. If it is assumed that the “fail-to-danger” mode is circuit breaker fail-closed with say 80% of failures in this mode, then a

best-estimate “dangerous” failure rate is

$$\begin{aligned} \lambda_d &= \lambda_b \cdot \alpha_D \Pi k_i \\ &= 4 \times 0.8 \times 2 = 6.4 \text{ failures}/10^6 \text{ h} \end{aligned} \quad (3)$$

For a system failure mode of “fail to operate on demand” and the assumption of a test interval (T) of 3 months (say 2000 h), the fractional dead time (mean unavailability) due to circuit breaker failure is

$$FDT = \frac{\lambda_d T}{2} = \frac{6.4 \times 2000}{2 \times 10^6} = 6.4 \times 10^{-3} \quad (4)$$

This is the probability of failure of a circuit breaker to disconnect the electricity supply on demand for input to a system fault tree. A similar approach would be adopted for the other pieces of equipment in the system with more detailed investigation focusing on failure data for the critical failure modes.

In-service Reliability Data

In-service reliability data analysis is required for monitoring equipment reliability performance during operation and to derive estimates of equipment failure rates for the in-house generic database. During analysis, it is important to differentiate between component and equipment failures. Components are items that can only fail once. Equipment, on the other hand, are repairable systems, and “failure” does not necessarily cause end of life; the piece of equipment can generally be repaired or restored to its previous operational state by replacement of the failed component. Different methods of data analysis and different definitions of the rate function are required for component and equipment reliability data analysis. For components, the rate function is termed the *hazard rate function* $h(t)$ (see **Mathematical Models of Credit Risk; Lifetime Models and Risk Assessment; Markov Modeling in Reliability**) and for equipment the *failure rate function* $z(t)$.

Component Data Analysis

Components, by definition, are not repairable; they have a finite life and lifetime characteristics can generally be represented by one of the standard distributions. The important point to note is that it is the characteristic of a population of identical components that fail randomly at different ages. Some sample populations exhibit decreasing hazard rate – generally because of quality control problems, others constant hazard rate – due to random shocks such as power surges, or increasing hazard rate – due to aging. When a component fails in a repairable system, it will be replaced by an identical new component with the assumption that the repairable system is restored to “as-good-as-new” (AGAN) condition. This assumption of “AGAN” is very important in component reliability analysis and includes the assumption that all observed events are from

components of the same type, and therefore that component lifetimes are independent and identically distributed (i.i.d.).

For detailed analysis of component failure characteristics, reliability engineers generally turn to Weibull analysis because of the distribution’s flexibility – it can model decreasing, constant, and increasing hazard rates. Graphical Weibull analysis (see **Reliability Growth Testing**) is preferred, particularly for small sample populations because of the snapshot it gives of scatter and the general structure of the data. Special probability plotting paper has been developed for the Weibull distribution. There are also a number of software packages available for determining the distribution of component failures.

Equipment Data Analysis

The analysis of reliability data from repairable systems can never be as precise as for items that are not repairable. Components are frequently bench tested under conditions where uncertainties concerning operating environment, component quality, age, etc., are closely controlled. Even when component data are extracted from operating system records, it can be assumed that failed components are replaced by new ones with the equipment considered only as the test bed.

When analyzing failure data from equipment in operating systems, however, the position is not so clear cut. Equipment, by definition, are repairable, and it is seldom possible to determine the age and condition of a piece of equipment at the start of surveillance. (Equipment that are not repairable are sometimes referred to as *supercomponents*.) Because of the diversity of components that make up equipment, the assumption of i.i.d. times to failure is no longer valid. Certain basic assumptions therefore need to be made, some of which are as follows:

- repairs are perfect, restoring the equipment to “as new” condition;
- failures occur at random, but at an underlying constant failure rate, λ . This implies that failures are the result of a homogeneous Poisson process (HPP) giving interfailure times t that are exponentially distributed, and thus failures in a specified time interval have a Poisson distribution.

Under the HPP model, the expected number of failures over any time period is λt and the probability

of observing an arbitrary number of failures x is given by the Poisson distribution where

$$P(X = x) = \frac{e^{-m} m^x}{x!} \quad (5)$$

and $m = \lambda t$. When the failure rate is not constant, the model is a nonhomogeneous Poisson process (NHPP).

The concept of increasing or decreasing failure rates for repairable equipment is completely separate from the issue of increasing or reducing hazard rates associated with components. Equipment can be simple or complex, but in either case, comprise a family of component parts. These components have different lifetime characteristics and unless there is a dominant failure mode, the mixing of component lifetimes and replacements when a component fails generally ensures that equipment failure rates quickly settle down to a constant value. However, and particularly with mechanical equipment, some components “bed-in” resulting in a gradually reducing failure rate as equipment age. On the other hand, other failure modes such as component wear may eventually lead to a gradually increasing failure rate. Monitoring changes in the reliability performance of systems and equipment to detect the onset of increasing or decreasing failure rates is a fundamental requirement for the availability-critical and safety-critical systems of an industrial plant.

Equipment Failure Characteristics

Component lifetime analysis is concerned with aging characteristics (*see Structural Reliability*). A component operates for a period of time and, for a population of components, these characteristics can be represented by the Weibull distribution in terms of the characteristic life (η) and shape factor (β) from which other parameters such as hazard rate $h(t)$ and mean time to failure (MTTF) can be determined. With this information, predictions can be made as to their likely reliability performance when installed in equipment.

The concept of “lifetime” is different for equipment, which operate within significantly longer time frames than their component parts. There will come a time for all industrial equipment when replacement is obviously essential because of the combined effects of the industrial and operating environments. However, for most of the time, a useful life period can be defined where the assumption of AGAN after component failure and replacement is valid. With this

assumption, the reliability characteristic of equipment can be categorized by a (constant) failure rate or its reciprocal – the equipment mean time between failures (MTBF) (*see Accelerated Life Testing*).

It is the author’s personal view that time between failures should always relate to operating time rather than operating plus repair time since repair strategies can vary significantly between different installations even within the same organization. Repair time data is, of course, important since it impacts on equipment, system, and plant availability, but its analysis needs to be considered separately from the analysis of failure time data. For failure data that meet these criteria, the MTBF is the total operating time of a population of equipment divided by the total number of failures.

Example

Three failures were recorded from a population of 10 pumps in a period of 1 year. Assuming an average repair time per failure of 8 h and AGAN after repair, then

$$\begin{aligned} MTBF &= \frac{(8760 \text{ h} \times 10 \text{ pumps}) - (3 \times 8 \text{ h})}{3 \text{ failures}} \\ &= 29192 \text{ h} \end{aligned} \quad (6)$$

Failure rate is the reciprocal of the MTBF so $\lambda = 1/(29192) = 3.4 \times 10^{-5} \text{ h}^{-1} = 0.3 \text{ failures/year}$.

Recalling the Poisson distribution as in equation (5) or in its more familiar form, the reliability $R(t) = e^{-\lambda t}$, when $x = 0$ since $(0.3)^0$ and $0!$ both equal unity.

Hence, the reliability (probability of no failure) of a pump in a period of 1 year is

$$R(t) = P(X = 0) = e^{-\lambda t} = e^{-0.3} = 0.74 \quad (7)$$

The probability of no failures in the population of 10 pumps during the year is

$$R(t) = e^{-(0.3 \times 10)} = 0.05 \quad (8)$$

And, taking this a step further, one can estimate the probabilities for $X = 1$, $X = 2$, etc.

For example,

$$P(X = 2) = \frac{e^{-m} m^x}{x!} = \frac{e^{-3.0} .3^2}{2 \times 1} = \frac{0.05 \times 9}{2} = 0.45 \quad (9)$$

This is the probability of exactly two failures in 1 year of operation.

Obviously the probability of more than one failure = $1 - R(t) = 1 - 0.05 = 0.95$

Reliability Data Collection

For the occasional *ad hoc* investigation triggered, say, by concern that some reliability problem has emerged concerning a piece of equipment, or a population of nominally identical items, investigations are generally short and clearly focused. In these situations, manual extraction of failure information from maintenance records and input to one of the standard spreadsheet programs is usually adequate. This methodology can also be acceptable for bench testing of components and equipment. However, when there is a routine reliability program with ongoing monitoring of critical systems and equipment, the use of database management programs such as ACCESS can be worthwhile. Standard database programs facilitate the organization of the basic inventory and event data into formats suitable for further processing by the use of spreadsheet programs or specialized management information and reliability analysis software. A typical information flow diagram for a reliability data collection and analysis system is shown in Figure 2.

Most of the information obtained from plant records are processed and stored in inventory and

event data files in standard formats. Inventory data comprises the engineering and process information required to identify the major items of equipment with respect to their design, operation, and maintenance features. Their location in the plant will be defined by a hierarchical code at plant, system, and equipment level.

The three main types of data needed in a reliability data system are as follows:

1. inventory data – defines the design and functional characteristics of the item;
2. failure event data – textual descriptions of each failure event (with additional codes to relate to the item's inventory) failure codes and operational and environmental conditions;
3. operating state data – dates and times of failure, operating state prior to failure, active repair and waiting times, etc.

Operating state data is seldom recorded, except for major equipment such as rotating machinery, hence, in most cases, estimates of operating time and time on standby are included with the failure event data.

It is worth making the point that many reliability data projects fail because of lack of attention to data quality. Before starting data collection, it is necessary to review the source of the data so that realistic objectives can be established within the available budget. A quality assurance plan should then be developed, which defines the objectives of the exercise and details the procedures to be followed in data collection and analysis. Finally, a quality audit should be carried out on completion, to assess the degree of success and to feed back processed data and recommendations to the host management. Feedback of information is essential for data validation and to ensure cooperation in future studies. In large schemes, it is worthwhile setting up a steering committee that meets at regular intervals to monitor progress on the study.

Reliability Demonstration

The purpose of a reliability demonstration test plan is to formally verify that a product meets a specified reliability requirement with a certain level of confidence. These plans are used in industry to provide assurance to consumers and external regulating bodies, as well as for internal quality control purposes. Consumers include both individual customers, as well as large companies that buy components from suppliers.

This article focuses on demonstration plans using binary (success/failure) data, also called *attribute testing* (see **Axiomatic Models of Perceived Risk; Repeated Measures Analyses**). While this is the most common scenario, there do exist other plans that use auxiliary information in addition to the success/failure data. One example is information on time at which the failures occurred (often called *time-to-failure data*). We discuss this case briefly later in the article.

The section titled “Demonstration Test Plans” provides an overview of zero-failure test plans and general k -out-of- n plans. The power behavior (probability of successful demonstration) is discussed in the section titled “Power of Demonstration Plans”. Two general approaches for increasing the efficiency of demonstration testing, Bayesian techniques and extreme testing, are reviewed in the section titled “Improving the Efficiency of Test Plans”. Additional information on demonstration testing and references to the literature can be found in [1, Chapter 10, pp. 466–486] and [2, Chapter 10.6, pp. 247–249]. Furthermore, several popular statistical software packages have modules for constructing demonstration test plans.

Demonstration Test Plans

Reliability demonstration plans (see **Comparative Risk Assessment**) have two specific requirements: a reliability target that has to be verified and a confidence level that has to be achieved. Reliability targets can be specified in terms of the reliability of a product at time t_0 , $R(t_0) = R_0$, or the design life corresponding to a reliability of R_0 , $L(R_0) = L_0$. Recall that $L(R)$ is the $(1 - R)$ th quantile. There is a one-to-one relationship between design life (see

Reliability Integrated Engineering Using Physics of Failure) and reliability, so we restrict attention to the reliability target R_0 throughout.

We begin with the zero-failure test plan, which is commonly used. Under this plan, a simple random sample of n product units are put on test until time t_0 . The test is said to successfully demonstrate the target reliability of R_0 if there are no failures during the test; otherwise, it is not successful. The sample size n is chosen to satisfy the confidence level requirement. Specifically, we must have

$$R_0^n \leq \alpha \quad \text{or} \quad n \geq \frac{\log(\alpha)}{\log(R_0)} \quad (1)$$

Letting $\lceil x \rceil$ be the smallest integer greater than or equal to x , we get the required sample size as

$$n = \left\lceil \frac{\log(\alpha)}{\log(R_0)} \right\rceil \quad (2)$$

The expression R_0^n in equation (1) corresponds to the probability of observing no failures out of n units when the true reliability is R_0 . This is sometimes called the “success-run” formula in the engineering literature [3].

The sample size is chosen so that the probability of observing zero failures is no greater than α when the true reliability is R_0 or smaller. Thus, if we do not observe any failures during the demonstration test, we can conclude with confidence (of at least $(1 - \alpha)$) that the required reliability must be at least as high as R_0 .

The actual probability of a successful demonstration depends on the true but unknown reliability R . We refer to this as power and discuss it in more detail in the next section. In practice, the value of R needs to be much higher than the target value R_0 in order to have a reasonable probability of successful demonstration.

The zero-failure plan is a special case of a k -out-of- n demonstration test plan. In this general case, one tests a simple random sample of n product units. The test is deemed successful if the number of failures is less than or equal to k . If we observe more than k failures, the test is unsuccessful. Here, the number of allowable failures k is fixed *a priori*. The sample size of the test plan is then chosen so that

$$\sum_{i=0}^k \binom{n}{i} (1 - R_0)^i R_0^{n-i} \leq \alpha \quad (3)$$

The expression on the left in equation (3) is the probability of getting k or fewer failures from testing n units with failure probability $(1 - R_0)$. This is simply the cumulative binomial probability.

Example 1 Suppose we need to demonstrate reliability of $R_0 = 0.9$ with 95% confidence. From equation (2), a zero-failure plan would require a sample of $n = 29$ units. On the other hand, a 1-out-of- n failure plan would require a sample of $n = 46$ units, since $n = 46$ is the smallest integer value for which equation (3) holds with $k = 1$.

A number of factors are involved in choosing the number of allowable failures k , some of which will be discussed later in the article. One concern is that the sample size n is not too large as to be unaffordable. As seen in Example 1, the sample size n increases with k . For this reason, the zero-failure plan ($k = 0$) is a popular choice.

Nevertheless, plans with $k > 0$ are also often used. These are sometimes preferred over zero-failure plans because they have an increased power or likelihood of being successful compared to zero-failure plans. The trade-offs between sample size and power are discussed in the next section.

Reliability demonstration plans are mathematically equivalent to certain hypothesis tests in statistics. Specifically, a reliability demonstration plan with $(1 - \alpha)$ confidence is equivalent to an α -level hypothesis test of $H_0 : R \leq R_0$ versus $H_1 : R > R_0$. A successful reliability demonstration plan corresponds to rejecting the null hypothesis. Further discussion of this equivalence can be found in [4, pp. 404–405].

Power of Demonstration Plans

In hypothesis testing, recall that the “power” of a test is defined as the probability of rejecting H_0 . We can analogously define the power for a k -out-of- n reliability demonstration plan as the probability that the demonstration test is successful, i.e., the probability of observing k or fewer failures.

The actual value of the power depends on the true reliability R and is given by

$$P(R) = \sum_{i=0}^k \binom{n}{i} (1 - R)^i R^{n-i} \quad (4)$$

Since R is unknown in practice, the power of the demonstration plan is also unknown. However, one can compute the power for various values of R and examine the power curve before conducting the test. Demonstration tests can be costly, and an unsuccessful test may result in loss of customer’s confidence, so one has to be reasonably certain up front that the test will be successful. The power $P(R)$ of a demonstration plan also depends on the choice of k (and hence also n) in a k -out-of- n plan. As mentioned, the power increases with k , but this, in turn, requires a larger sample size n .

Example 2 Consider again the set up in Example 1 with $R_0 = 0.9$ and confidence level of 95%. Suppose that the true reliability for this product is $R = 0.99$. The zero-failure plan with sample size of $n = 29$ has a power of 0.75. On the other hand, the $k = 1$ -failure plan requires a larger sample size of $n = 46$, but also has a larger power of 0.92. These comparisons can be seen in the first plot in Figure 1.

In practice, test planners must balance the need for a large power with the cost of a large sample size. Typically, they calculate the power in equation (4) for different values of the true reliability R and different plans before deciding on the best plan to use. In many cases, a specific minimum power requirement is used to determine the values of k and n . For instance, in Example 2, if the test planner required that the power be at least 0.95 when the true unknown reliability is 0.99, then neither the zero-failure plan nor the $k = 1$ -failure plan would be adequate. Rather, the plan with the smallest sample size n that meets this requirement is the $k = 2$ plan, which requires a sample size of $n = 61$ (as displayed in the first plot in Figure 1). If this sample size is not affordable, the test planner would either need to lower the power requirement, decrease the required confidence $(1 - \alpha)$, or use other testing schemes. (See, for example, the discussion on Bayesian techniques and extreme testing later in this article.)

Note that while the terms *power*, *level*, and *confidence* are common in statistics, engineers typically use the terms *manufacturer’s risk* or *producer’s risk*, and *consumer’s risk* (see, for example [5, pp. 244–245]). Producer’s risk is the probability or risk of rejecting the product (failing the demonstration test) when the product reliability meets or exceeds the target. Consumer’s risk, on the other hand, is the probability or

Figure 1 Power of demonstration plans for different values of k and R_0

risk of accepting the product when the true reliability does not meet the target value.

Figure 1 provides a comparison of the power of $k = 0$, $k = 1$, and $k = 2$ test plans for different values of R_0 as a function of the true unknown reliability R with level $\alpha = 0.05$. The four plots display the power of these test plans for R_0 equal to 0.9, 0.95, 0.99, and 0.999, respectively. In each plot, the x axis begins at R_0 and ends at 1. Each curve begins at $\alpha = 0.05$ on the y axis since the power, by definition, is equal to α when R is equal to R_0 . Similarly, each curve ends at 1 on the y axis since the power of any demonstration plan is necessarily equal to 1 when R is equal to 1. The curves for each value of k are remarkably similar across the four graphs despite the different sample sizes (and different scales for the x axis). As noted earlier, larger values of k lead to larger power, but also require larger sample sizes. Some software packages, such as Minitab (Version 14.0) can be used to compute sample size and power calculations for reliability demonstration plans.

Improving the Efficiency of Test Plans

In many cases, the number of units required for the demonstration plans can be prohibitively large. In this section, we discuss two alternative approaches that use additional information to reduce sample sizes and test costs. See also [1, Chapter 10] for sequential tests.

Extreme Testing

Increasing test time or overtesting (also called *bogey testing*) is a common approach for reducing sample sizes (see, for example [2, Chapter 10.6] and [3]). Suppose the goal is to demonstrate reliability of $R(t_0) = R_0$ at time t_0 . Instead of testing units only until time t_0 , one can test them for a longer period of time, say $t_1 > t_0$. If we have a parametric model that relates the reliability at time t_0 to reliability at time t_1 , we can trade-off sample size for increased test time (see **Accelerated Life Testing**). This approach is beneficial if test time is relatively cheaper than test units.

Example 3 Consider again Example 1 with $R_0 = 0.9$ and $\alpha = 0.05$, where the traditional zero-failure plan requires $n = 29$ units. Suppose R_0 corresponds to reliability at time $t_0 = 1$ million cycles of operation. In this situation, suppose we can test the units until time t_1 with $t_1 > t_0 = 1$ million cycles. For the sample-size calculation, we need to know the form of the underlying reliability or failure-time distribution. If it is exponential, the sample-size formula is

$$n = \left\lceil \frac{s \log(\alpha)}{\log(R_0)} \right\rceil \quad (5)$$

where $s = t_0/t_1$ [2, p. 248]. This yields $n = 15$ for $t_1 = 2$ million cycles and $n = 10$ for $t_1 = 3$ million cycles. For the Weibull distribution with known shape parameter β , the sample-size formula becomes [2, p. 248]

$$n = \left\lceil \frac{s^\beta \log(\alpha)}{\log(R_0)} \right\rceil \quad (6)$$

where again $s = t_0/t_1$.

It is natural to wonder why one should not continue increasing the test time to reduce the sample size all the way to $n = 1$. One reason is that the assumption about the failure-time distribution is less likely to hold in the extreme tail, so one must be cautious in increasing the test time much beyond the target condition. Additionally, testing for a very long period can introduce failure modes that are not present at the target condition.

There are also expressions for sample sizes for general k -out-of- n plans under overtesting, but they are more involved. Some software packages, such as Minitab (Version 14.0), have capabilities for computing the sample sizes for selected log-location-scale distributions, assuming that the scale parameter is known.

The authors of [6] generalize approaches such as overtesting, which seek to improve demonstration test efficiency through increasing failure probability. They use the term *extreme testing* or (“X-testing” for short) to describe such methods. Another well-known example of X-testing is the use of accelerated stress conditions to induce early failures. While this is common with time-to-failure data, it can also be useful with binary data. However, one needs information about the acceleration model (see **Competing Risks**), which requires testing at more than one stress level. The authors of [6] discuss this and other,

newer approaches to X-testing. These include testing “weaker units”, the use of series-system structures for testing components, etc. The fundamental idea in X-testing is that it is often more efficient to demonstrate reliability under “extreme” conditions that correspond to a lower reliability target. The X-transform $\tau(\cdot)$ maps R , the reliability under standard conditions, to $\tau(R)$, the reliability under the extreme conditions. For suitable X-transforms, this leads to demonstrating a lower reliability target $\tau(R_0)$. X-testing assumes that the X-transform $\tau(\cdot)$ is known. A number of situations in which this is feasible are discussed in [6]. For example, in the overtesting case with the exponential distribution we have

$$\tau(R) = e^{s \log(R)} \quad \text{or} \quad \log(\tau(R)) = s \log(R) \quad (7)$$

where $s = t_0/t_1$. This requires information about the failure-time distribution which can be obtained from previous studies.

An important consideration in using X-testing is the effect on the power of the demonstration plan. In the case of zero-failure plans, the power of an X-test can be equal to, smaller than, or even larger than the power of the corresponding traditional plan (despite having a smaller sample size). The power of the X-test is completely determined by its X-transform, which, in turn, depends on the methodology used to induce failures. The authors of [6] discuss different methods of inducing failure and show that many of them lead to location or scale X-transforms.

Bayesian Techniques

The Bayesian approach provides a formal framework for introducing prior knowledge about the product reliability R and using it to reduce test costs or sample sizes. This knowledge is represented through a prior probability distribution on R , and may come from past testing or even expert opinion.

To describe the formulation, suppose the prior distribution of R is uniform on $(0, 1)$. (This is a conservative case; in practice, the prior information will be more informative.) Conditional on the value of R , the number of failures among n units tested is (as before) binomial with probability $(1 - R)$. Let us consider first the simple case of zero-failure plans. If we observed zero failures, the posterior probability density of R , given this event, turns out to be $(n + 1)R^n$. Thus, the posterior probability that R is less than the target value R_0 is $\int_0^{R_0} (n + 1)R^n dR = R_0^{(n+1)}$. Under

the Bayesian formulation, we choose the sample size n so that this posterior probability is less than or equal to α . In this particular case, this leads to $R_0^{(n+1)} \leq \alpha$, so

$$n = \left\lceil \frac{\log(\alpha)}{\log(R_0)} \right\rceil - 1 \quad (8)$$

which is one less than the classical expression in equation (2). This reduction in sample size may seem counterintuitive since the uniform prior could be viewed as conservative. Priors with more information (with more probability mass at higher reliabilities) will result in substantially smaller sample sizes.

The Bayesian versions of k -out-of- n plans are obtained similarly. As before, k is fixed *a priori*, and the sample size n is then determined. Given a prior distribution, we can compute the posterior probability density of R , conditional on observing k or fewer failures. Let $p(R; n, k)$ denote this posterior probability density function of R . Then, we choose n so that

$$\int_0^{R_0} p(R; n, k) dR \leq \alpha \quad (9)$$

For more details, see [1, Chapter 10, pp. 466–486].

Priors in the beta family of probability distributions are especially convenient since the resulting posteriors will also be in the β family. However, recent advances in Bayesian computing and the use of (*see Nonlife Loss Reserving; Bayesian Statistics in Quantitative Risk Assessment*) methods Markov Chain Monte Carlo (MCMC) allow us to also handle more general prior distributions, so the appropriateness of the prior for the problem at hand should be the main concern.

Detractors of the Bayesian approach may characterize the selection of a prior distribution as “making up data,” while proponents of the approach would point out that not all information comes in the form of data and that many users of statistical methods interpret results in a Bayesian manner anyway. In any case, it is certainly true that prior information can greatly reduce the required sample size for a reliability demonstration test.

Concluding Remarks

The current emphasis in industry is on building quality and reliability into the product up front. On the

other hand, reliability demonstration planning shares some of the philosophy and terminology with sampling inspection for quality assurance, which has fallen out of favor. Nevertheless, reliability demonstration remains an important part of current industrial practice for verifying customer requirements or government regulations. Reliability demonstration test plans are also used internally in many companies, although these demonstration tests may be used informally, without requirements on confidence levels.

Because demonstration test plans can be costly in terms of test units or test time, there is a need to identify and develop alternative methods that can reduce test costs. We have discussed two classes of approaches here, but both use only the binary (success/failure) data. Even with these k -out-of- n plans, if $k > 0$, we may have information on the actual time of failure, which can be exploited. For example, if we observe one failure, then knowing whether the failure occurred early in the test or just before the end of the test could provide useful, additional information.

Other methods of increasing efficiency include using the actual failure-time data to estimate the reliability and then computing appropriate confidence bounds to demonstrate that the target is met. In applications with very high reliability, one may need to use accelerated testing to induce failures and observe the failure times. An alternative approach that is becoming more common is the collection and analysis of degradation data. All of these methods, like the X-testing approach discussed in this article, require additional assumptions such as knowledge of the failure-time distribution, the acceleration model, the X-transform, and so on. Many customers and regulatory agencies are often reluctant to accept these assumptions, leading to the continued reliance on traditional demonstration tests.

Reliability Growth Testing

The first prototypes of a new product generally contain design, manufacturing, and/or engineering flaws that prevent specified reliability requirements to be met. Reliability growth is the process by which the reliability problems are identified and corrected by introducing modifications in the product design and/or manufacturing process. Accordingly, the reliability of the product grows as the product goes through successive stages of the development program.

Permanent actions addressed to prevent reliability problems both of tested prototypes and of all future copies of the product constitute a reliability growth. Reworks, screening of units with lower reliability, and temporary fixes do not constitute reliability growth.

Reliability growth programs should be carried out for all new products and all existing products subject to major design changes, to reduce the risk in launching new technologies, and to avoid mass production of products that do not meet reliability requirement and customer satisfaction. Clearly, early implementation of a reliability growth program can minimize the impact of design and/or process changes on production scheduling and total cost of the product, because redesigning the product late in the development phase or retrofitting products already in the field is very expensive.

Implementing correctly reliability growth programs can produce increased quality and reliability of product and process, reduced costs and risk of product development, improved customer satisfaction, improved market position, and reduced warranty claims and costs. A collateral result is the increased knowledge and experience gained by the reliability team on the identification and solution of reliability problems.

The degree of possible improvement in product reliability depends on the underlying technology of the product, the available resources, and the knowledge of the reliability team. The underlying technology is an obvious limiting factor, as well as economic and human resources that are always limited, thus conditioning the management strategies toward performing tests and introducing reliability improvements. For example, limited resources may prevent the team from introducing very expensive

modifications. The knowledge of the reliability team affects both the ability to identify the cause of observed failures and the degree of effectiveness of implemented actions, because a corrective action does not always entirely eliminate a failure mode from occurring again, even if the cause has been identified.

The limitation of resources and development time compels the reliability growth process to be as efficient as possible. Clearly, efficiency is a relative concept and the attained improvement has to be compared with the reliability level at the beginning of testing and to the reliability goal.

In general, a reliability growth program may have more than one reliability goal. For example, one goal may be associated with all the failures occurring during the warranty period and the second goal would be to achieve a very low probability of occurrence of safety related failures.

Of course, the reliability growth has to be monitored to compare the actual reliability level to the target value and to estimate whether the development program is progressing as scheduled. If the achieved improvement is less than the planned one and the reliability goal is not going to be met, then new strategies should be considered, by devoting a larger amount of resources to the program.

Although reliability growth generally refers to improvements in products reliability, a very important field where reliability growth programs find large application is the control of industrial accidents (*see Human Reliability Assessment; Experience Feedback*) [1].

Reliability growth programs generally consist of a number of test stages. Each stage can be viewed as a distinct period of time when the product is subjected to testing and subsequent corrective actions (or fixes). During each stage, one of three basic types of test and fix programs may be carried out, the main distinction among them being when fixes are introduced into the products. Fixes can be implemented each time a failure occurs and the failure cause is identified, or can be delayed and implemented in block at one time, typically at the end of each stage (*delayed fixes*). The three types of testing program are as follows: (a) test-analyze-and-fix (TAAF) (*see Hazard and Hazard Ratio*) program, when fixes are implemented just after the failure occurrence, (b) Test-Find-Test (TFT), when all fixes are delayed, and (c) TAAF program, with some delayed fixes. The TAAF program is the one

with a more or less smooth, continuous growth curve, because each fix introduced during testing generally produces a small increase in product reliability. On the contrary, the TFT produces significant jumps in the product reliability, resulting in a step function [2].

In general, reliability growth programs are carried out on a number of identical prototypes, manufactured at the same time. However, in some cases, especially when the products are very expensive and their manufacturing time is very long (i.e., locomotives, airplanes, industrial plants, etc.), the development program involves preseries products that are put on test progressively, as soon as they are manufactured. In this case, design and/or process defects, discovered during the development program, are corrected and product design and/or manufacturing process improve as the program goes on. Thus, the initial reliability of tested products is not the same: a product put on test at the beginning of the program has more defects than one product put on test when the program is going to end (see, for example [3]).

The reliability growth of a product can be expressed in terms of quantities such as the decrease in the rate of occurrence of failures $\rho(t)$ (see **Repairable Systems Reliability; Near-Miss Management: A Participative Approach to Improving System Reliability**), the decrease in the number of failures, and the increase in the mission success probability. These quantities are generally mathematically related and can be derived from each other. The changes in these quantities, as a function of the testing time, are generally referred to as *reliability growth trends* and are described through statistical models called *reliability growth models* (see **Repairable Systems Reliability; Reliability Data**). Depending on the failure mechanisms, the strategy adopted to improve the product reliability, and the kind of observed data, different models can be utilized. In the next section, a number of reliability growth models are briefly illustrated.

Reliability Growth Models

The general term, reliability growth models, is usually used to denote those models that are specifically applicable to the analysis of time-to-failure data. In this case, the reliability growth is generally modeled through stochastic point processes under the assumption that failures are highly localized events that occur

randomly in the continuum. Reliability growth model for time-to-failure data can be roughly classified into *continuous* and *discontinuous* models, and are briefly discussed in the following.

However, a broad class of models is devoted to the analysis of one-shot systems (such as guns, rockets, and missile systems) whose relevant data consist of sequences of dichotomous success–failure outcomes from successive testing stages. A complete survey of such models, generally referred to as *discrete* reliability growth models, can be found in [4].

Continuous Models

Continuous models are mathematical tools able to describe the *overall* trend in product reliability, resulting from the repeated applications of corrective actions. They are commonly applied in TAAF programs where the underlying failure process can be thought of as a decreasing stepwise function with test time (whose jumps depend on the effectiveness of corrective actions) that is fitted by a continuous curve representing the overall trend (see Figure 1).

The most commonly used of such models is the power-law process (PLP) (see **Repairable Systems Reliability**) [1], often known as the *Duane model* [5], whose intensity function $\lambda(t)$

$$\lambda(t) = \frac{\beta}{\alpha} \left(\frac{t}{\alpha} \right)^{\beta-1}, \quad \alpha, \beta > 0 \quad (1)$$

numerically equal to the rate $\rho(t)$, is a decreasing function with the test time t when $\beta < 1$. The expected number of failures up to t , say $M(t) = \int_0^t \rho(x) dx = (t/\alpha)^\beta$, is linear with t in a log–log scale.

The growth parameter β measures the management and engineering efforts in eliminating the failure modes during the development program. Small β values (e.g., $\beta \leq 0.5$) arise when an aggressive program is conducted by a knowledgeable team.

If the reliability growth program ends at the time T and no further improvement is introduced afterward, then the reliability level of tested prototypes at time T will characterize the reliability of the product as it goes into production. Besides, the intensity function of the product as it goes into production is generally assumed to remain constant during the so-called useful life period (see **Environmental Exposure Monitoring; Hazard and Hazard Ratio**)

Figure 1 The underlying failure process in a TAAF program and its overall trend, where the product reliability in each testing stage i is measured by the rate of occurrence of failures

and equal to the intensity $\lambda_T \equiv \lambda(T)$ at the end of the development program [6]. The *current reliability* $R(\tau)$ (see **Repairable Systems Reliability; Mathematics of Risk and Reliability: A Select History**), i.e., the probability that the next failure occurs after τ during the useful life period, is

$$R(\tau) = \exp(-\lambda_T \cdot \tau), \quad \tau > 0 \quad (2)$$

which gives the success probability of a new product for a mission of fixed duration τ , too.

The PLP enjoys large popularity, partly because of the simplicity of inference procedures. Indeed, given the first n successive failures times observed during the test time T , say $t_1 < t_2 < \dots < t_n \leq T$, one can easily obtain graphical estimates of parameters by exploiting the linear behavior of $M(t)$ with t in a log-log scale [7]. Again, the maximum-likelihood (ML) estimators of parameters β and α are in closed form:

$$\hat{\beta} = \frac{n}{\sum_{i=1}^n \ln(T/t_i)} \quad \text{and} \quad \hat{\alpha} = \frac{T}{n^{1/\hat{\beta}}} \quad (3)$$

and exact confidence intervals for β can be easily obtained because $2n\beta/\hat{\beta}$ is a χ^2 random variable (r.v.) both in failure-truncated sampling (where

$T \equiv t_n$) and in time-truncated sampling (see **Detection Limits**), with $2(n-1)$ and $2n$ degrees of freedom, respectively [1]. Likewise, in failure-truncated sampling, one can obtain exact confidence intervals for $\lambda_n \equiv \lambda(t_n)$ and $R(\tau)$ by exploiting the result

$$\frac{\lambda_n}{\hat{\lambda}_n} \sim \frac{Z \cdot S}{4n^2} \quad (4)$$

where Z and S are independent χ^2 r.v.'s with $2(n-1)$ and $2n$ degrees of freedom, respectively [8]. Table 1 of [9] allows one to obtain exact confidence intervals for λ_n and $R(\tau)$. For time-truncated samples, approximate confidence intervals for λ_T and $R(\tau)$ can be obtained by using Table 2 of [9].

For the case of failure-truncated sampling, one can predict the *current lifetime* τ (see **Persistent Organic Pollutants**) by exploiting the result that $V = \hat{\lambda}_n \cdot \tau$ is a pivotal quantity, whose percentiles are given in Table 1 of [10] for selected n values.

For illustrative purposes, let now consider the $n = 14$ failure times (in a failure-truncated sampling) of a complex type of aircraft generator subject to TAAF

Table 1 Failure times in hours of aircraft generator^(a)

10	55	166	205	341	488	567

^(a) Reproduced from [11]. © American Statistical Association, 1998

program [11] (see Table 1). The product reliability is measured by the success probability for a mission of $\tau = 100$ h, and the reliability requirements are met if the lower 90% confidence limit for $R(100)$ is greater than 0.75. By using equations (3), the ML estimates are $\hat{\beta} = 0.613$ and $\hat{\alpha} = 61.9$ h, and the 90% confidence interval for β is (0.337, 0.851), thus providing empirical evidence that the reliability growth program has been effective. The ML estimates of λ_n and $R(100)$ are $\hat{\lambda}_{14} = 0.00187 \text{ h}^{-1}$ and $\hat{R}(100) = 0.830$, respectively. By using Table 1 of [9], the upper 90% confidence limit for λ_n is $\lambda_U = 0.00187/0.7087 = 0.00263 \text{ h}^{-1}$, from which the lower 90% confidence limit for $R(100)$ results in $R_L(100) = \exp(-\lambda_U \cdot 100) = 0.768$. Then, at the end of the development program the product meets the reliability requirements.

Another model frequently used in TAAF programs is the log-linear process (LLP) [12] whose intensity function:

$$\lambda(t) = \exp(\alpha + \beta t) \quad -\infty < \alpha, \beta < \infty \quad (5)$$

is more realistically equal to the positive value of $\exp(\alpha)$ at $t = 0$. In the reliability growth context, when $\beta < 0$, the LLP yields a defective distribution for the time to first failure (the mean of the first failure time is infinity).

Both the PLP intensity and the LLP intensity tend to zero as t approaches infinity, and hence such models cannot be used, for example, to analyze data collected during a TAAF program followed by a demonstration test dedicated to verify the attainment of reliability goals. Indeed, during the demonstration phase the rate of occurrence of failures is expected to be roughly constant and greater than zero. In this case, a more realistic model is the three-parameter LLP, whose failure intensity $\lambda(t) = \exp(\alpha + \beta t) + c$ ($-\infty < \alpha < \infty$, $\beta < 0$, and $c > 0$) approaches more realistically to the positive value of c as the test time increases.

When the initial reliability of the prototypes depends on the age of the manufacturing process, the *process-related reliability growth* model of [13] can be used. This process describes the design process through a PLP (with $\beta < 1$) and assumes that the scale parameter α is not constant, but depends on the age X of the manufacturing process when the prototype is manufactured.

Discontinuous Models

Discontinuous models are able to describe both TAAF programs and the cases where some or all of the fixes are delayed.

In case of TAAF program, Sen [11] and Pulcini [14] proposed two parametric models that assume that the failure intensity λ_i is constant during testing stage i ($i = 1, 2, \dots$), so that the resulting plot of the failure intensity as a function of test time is a nonincreasing series of steps. Thus, the interfailure times $t_i - t_{i-1}$ are independent exponential r.v.'s with mean $1/\lambda_i$. In particular, in [11] $\lambda_i = (\eta/\theta)i^{1-\theta}$ ($\eta > 0$ and $\theta > 1$), where the ratio η/θ is the starting failure intensity of the product. In [14], $\lambda_i = \mu\delta^{i-1}$ ($\mu > 0$ and $0 < \delta < 1$), where μ is the starting failure intensity, the *growth parameter* δ is equal to the ratio λ_{i+1}/λ_i , and hence $1 - \delta$ is the fraction of failures eliminated by each corrective action.

In case of delayed fixes, the reliability growth model depends also on the assumptions regarding failure mechanisms and repair policy during each development stage, because more than one failure can occur during each stage.

The nonparametric model of [15] assumes that the prototype is perfectly repaired at failure during each stage of a TFT program. Thus, the failure process is a series of renewal processes, where the probability distribution governing the interfailure times changes stage by stage. The model in [16] assumes that the interfailure times during each stage are exponentially distributed, so that the failure process is a series of homogeneous Poisson processes (see **Repairable Systems Reliability**) whose failure intensity decreases stage by stage.

Both these models can be used for nonrepairable or simple products, but are not adequate for the analysis of complex repairable systems subject to TFT program, for which the discontinuous model proposed by Ebrahimi [17] and Calabria *et al.* [18] is more suitable. This model assumes that the prototypes can experience deterioration with operative time during each stage, are substituted with new improved copies at the beginning of each stage, and are minimally repaired at failure during each stage. The failure process in each stage is described by a PLP with $\beta > 1$, where the parameter β measures the deterioration rate of the system within each stage and is assumed to be constant over stages (fixes do not alter the failure mechanism). The scale

Figure 2 Hypothetical behavior of the failure intensity of a deteriorating system undergoing a Test-Find-Test program

parameter α increases stage by stage, as a result of reliability growth. Figure 2 depicts a hypothetical behavior of the failure intensity during such a TFT program. ML estimates can be found in [17, 19], whereas [18] proposes a Bayesian approach that is mainly addressed to the solution of a decision-making problem (to accept the current design of the equipment for mass production, or to continue the development program).

Reliability Integrated Engineering Using Physics of Failure

Reliability

Reliability is the ability of a product to perform without failure and within specified performance limits, for a specified time, in its life-cycle application conditions. The development of a reliable product is not a matter of chance or good fortune; rather, it is a rational consequence of conscious, systematic, and rigorous efforts conducted through the entire life cycle of the product. Acceptable product reliability can only be assured through robust product designs, capable processes that are known to be within tolerances, and qualified components and materials from vendors whose processes are also capable and within tolerances. Quantitative understanding and modeling of the relevant failure mechanisms can guide design, manufacturing, and the planning of test specifications and tolerances.

Physics of failure (PoF) is a methodology for reliability assessment, which is fundamental to design for reliability (DfR) (see **Reliability Optimization**), reliability prediction, test planning, and prognostics. The objective is to design and test a product using parts and materials that have been sufficiently characterized in terms of performance over time when subjected to the manufacturing and application (environmental and operational) profile conditions. To carry out this objective, it is necessary to identify the potential mechanisms of failure, such as corrosion, fatigue, hot carriers, and electromigration, to name a few. The assessment of failure mechanisms forms the foundation for PoF (see Table 1 for definitions).

A failure mechanism (see **Failure Modes and Effects Analysis; Common Cause Failure Modeling**) is a chemical, mechanical, thermodynamic, or other process that is the root cause of the failure occurrence. Whether a specific failure mechanism will arise in a product and cause failure will depend on the environmental load conditions (e.g., temperature, humidity, contaminants, and radiation), and the operating load conditions (e.g., voltage, current, and generated temperature). The failure mechanisms will also depend on the product materials and the product

composition, including how the materials are composed and connected.

Failure sites are the locations where failure mechanisms precipitate. In electronic products, failure sites include semiconductor chips, component interconnects, circuit board metalization, interconnects (solder joints) between the component and the printed circuit, and external connections, such as connector and wiring.

The PoF methodology uses failure mechanism models (sometimes called *PoF models*) to assess the onset of potential failure mechanisms at specific failure sites in the product. A failure mechanism model will depend on the product composition and the stress (especially at the failure site). Stress is defined as the *intensity of a load* (e.g., electrical, thermal, mechanical, and chemical) at a failure site. The result of the PoF model is a probabilistic time to failure for a percentage of likely products to fail due to the failure mechanism.

The Physics-of-Failure Methodology

PoF methodology requires a set of information as input on which it performs a series of analysis and as a result provides a set of outputs that can be customized depending on the application. This section describes the steps, as shown in Figure 1, in this process.

Inputs

The PoF methodology requires inputs of the hardware configurations and the life-cycle profile (LCP) of the product under analysis. The details of the inputs may vary depending on the stage of product development.

Hardware Configurations. A product consists of a number of components and subassemblies working together to deliver the overall function of the product. Each subassembly may consist of lower level assemblies that are also interconnected. The architecture of a product describes the physical and functional relations between the subassemblies. The hardware configuration of the product being evaluated by PoF method describes the design of the components and subassemblies and the product architecture. It may also include the effects of the manufacturing processes on the final product in the form of tolerances on the dimensions and material properties.

This situation may require the elastic modulus of the connector elements, loading elements, and their housings to determine the contact force and its degradation pattern. Properties for common materials used in electronic products can be found in [1, 2].

Products are not normally produced by a single manufacturing process, but require a sequence of different processes to achieve all the required attributes of the final product. The manufacturing process applies stresses on materials, may produce residual stress, and may even modify some of material properties. For example, lead-free reflow profile can change the thermophysical properties of a printed circuit board. The variations in geometry and material properties caused by different manufacturing processes need to be inputs to the PoF methodology.

Life-Cycle Profile (LCP). Loads applied to the product during its life cycle from environment and operation drive the processes that lead to product degradation and failure. The life cycle of a product includes manufacturing and assembly, testing, rework, storage, transportation and handling, operation (e.g., modes of operation and on-off cycles), repair, and maintenance. The life-cycle loads include thermal (steady-state temperature, temperature ranges, temperature cycles, and temperature gradients), mechanical (pressure levels, pressure gradients, vibrations, shock loads, and acoustic levels), chemical (aggressive or inert environments, ozone, pollution humidity levels, contamination, and fuel spills), physical (radiation, electromagnetic interference, and altitude), and/or operational loading conditions (power, power surge, heat dissipation, current, and voltage spikes). These loads, in various combinations, can influence the reliability of the product. The extent and rate of product degradation depend upon the nature, magnitude, and duration of exposure to such loads.

An LCP is a time history of events and conditions associated with an item of product from its release from manufacturing to its removal from service. The life cycle should include the various phases that an item will encounter in its life, such as handling, shipping, and storage prior to use; mission profiles while in use;^a phases between missions, such as standby or storage, transfer to and from repair sites and alternate locations; and geographical locations of expected deployment.

LCP influences the stress levels on the product and failure mechanisms that will be active on a product. For example, the frequency of use may determine the number of temperature cycles to which a product is exposed on a daily basis. During transportation, the product may be subjected to substantial vibration loading. In storage, elevated humidity levels may be present. Under operation, an electrical bias may exist between isolated conductors. The level of temperature, vibration, humidity, and voltage potential may be inputs to determine thermomechanical stress, mechanical strain, moisture content, and dendritic growth, respectively.

It is also necessary to identify the critical loads to a product under certain conditions. A product will experience numerous loads, but it is not always necessary to process all the loads in the analysis steps. Some of the loads will play major roles in activating and accelerating the failure of the product, while other loads can be ignored. For example, radiation can often be ignored for ground-based electronic products, since the radiation level is too low to produce any effect to the function of the product or cause any damage. The same load may also be considered to have different criticality for different products under different conditions. For example, a mechanical shock caused by dropping a cell phone onto the hard ground, which is critical to the electronic parts in the cell phone, will have no effect on a tire and can be ignored. The loads that can or cannot be ignored depend on the critical failure mechanisms that are identified in the analysis step.

Analysis

PoF analysis steps determine the failure mechanisms that are active on a product and evaluate the effects of those failure mechanisms on the possible failure sites of the product. The analysis steps are conducted in sequence and the result of one step is used as a part of input to the next step.

Failure Modes, Mechanisms, and Effects Analysis (FMMEA). Failure modes, mechanisms, and effects analysis (FMMEA) is an essential step in the PoF analysis that uses hardware configuration and the LCP to identify critical failure mechanisms. FMMEA utilizes the basic steps in developing a traditional FMEA in combination with knowledge of PoF. It then uses LCP to identify active stresses and select

Figure 2 FMMEA methodology

the potential failure mechanisms. Knowledge of load type, level, and frequency combined with failure site are used to prioritize failure mechanisms according to their severity and likelihood of occurrence. Figure 2 is a schematic diagram of FMMEA.

FMMEA is based on understanding the relationships between product requirements and the physical characteristics of the product (and their variations in the production process), the interactions of product materials with loads (stresses at application conditions), and their influence on the product's susceptibility to failure. FMMEA combines life-cycle environmental and operating conditions and the duration of the intended application with knowledge of the active stresses and potential failure mechanisms. Potential failure mechanisms are determined on the basis of appropriate available mechanisms corresponding to the material system, stresses, failure modes, and causes.

FMMEA prioritizes the failure mechanisms on the basis of their occurrence and severity to provide guidelines for determining the major operational stresses and environmental and operational parameters that must be accounted for in the design or be controlled. LCP is used for evaluating failure susceptibility. If certain environmental and operating conditions are nonexistent or generate a very low-level stress, the failure mechanisms that are exclusively dependent on those environmental and operating conditions are assigned low occurrence. Severity ratings

are obtained from the failure modes associated with the mechanism. The high-priority failure mechanisms identified through combination of occurrence and severity are the critical mechanisms. Each critical failure mechanism has one or more associated sites, modes, and causes in an FMMEA result.

The basic categories of failures are overstress (i.e., based on stress strength interference) and wear out (i.e., based on damage accumulation); they are often identified through a mode of going beyond performance tolerance (e.g., excessive propagation delays). Overstress and wear-out failures generally result from irreversible material damage; however, some overstress failures can be caused by reversible material damage (e.g., elastic deformation) [3]. Failures can also be broadly categorized by the nature of the loads that trigger or accelerate the mechanisms. Examples of both failure types for electronic assemblies are given in Table 2.

Failure models (*see Probabilistic Risk Assessment*) are used as tools to assess failure propensity. There are two different categories of models: analytical models and PoF models. PoF methodology needs inputs of PoF-based models rather than analytical models. Many models, such as the Arrhenius model, the Coffin–Mason model and the Steinberg model, exist for predicting the behavior of components and products. Different models have different associated assumptions, which limit their applications to specific ranges of conditions.

Table 2 Examples of overstress and wear-out failure mechanisms for electronic products^(a)

Failure mechanism			
Overstress (environmental extreme)		Wear out (life)	
Mechanical	Yield, fracture, and delamination	Mechanical	Fatigue, creep
Thermal	Softening due to glass transition	Thermal	Diffusion voiding
Electrical	Electrical overstress, electrostatic discharge, and dielectric breakdown	Electrical	Electromigration, conductive filament
Radiation	Single-event upsets	Radiation	Embrittlement charge tapping
Chemical	Etching	Chemical	Corrosion, dendrites, and intermetallic growth

^(a) Reproduced from [4]. © IEEE, 2003

In PoF models, the stresses and the various stress parameters and their relationships to materials, geometry, and product life are considered. Each potential failure mechanism is represented by one or more of the prevalent models. For electronic products, there are many PoF models describing the behaviors of components like printed circuit boards, interconnections, and metalizations under various conditions, such as temperature cycling, vibration, humidity, and corrosion. A model should provide repeatable results, reflect the variables and interactions that are causing failures, and predict the behavior of the product over the entire domain of its operational environment. This type of model allows development of accelerated testing and may help reduce the number of test runs.

Many PoF models are available in the literature, such as strain-range-based model for solder joint fatigue [5], which describes temperature-cycle-induced solder interconnect fatigue; Black's model and its variations [6], which describes the electromigration in semiconductor devices; the Fowler–Nordheim model [7], which describes the time-dependent dielectric breakdown due to tunneling in gate oxide devices; and Pecht and Rudra model [8] that described conductive filament formation in printed circuit board. Models applicable to electronic products are available in [9–11]. If no models are available or if the models are found to be not applicable to specified failure sites and loads, then new models can be developed by using controlled experiments that identify the design and environmental

factors governing failure and the mathematical relationship linking those factors to the time to failure.

Stress Analysis. Stress analysis is used to convert the loads on the system to stresses at the potential failure sites. The product's life-cycle loads and configuration information are inputs to the stress analysis process. Stress analysis is conducted for the stresses that drive the critical failure mechanisms identified by FMMEA. For electronic products, thermal analysis, thermomechanical analysis, and vibration analysis are often performed to determine the inputs for the relevant failure models.

Thermal analysis is used to determine the temperature distribution within a product. For a printed wiring board (PWB) in an electronic product, the thermal analysis will output the temperature on and within the board, and at electronic part cases and junctions. Thermal analysis involves the solving of heat transfer equations for three fundamental modes of heat transfer: conduction, convection, and radiation. Thermal analysis may be transient or steady state. In most cases, steady-state thermal analysis results provide sufficient inputs to identified failure models. For example, a temperature cycle is usually defined to occur between a powered-on operating state and a powered-off state. Here, a steady-state thermal analysis may be used to establish the powered-on state. In some instances, the transient behavior may be important. For example, if a significant delay in the change of temperature occurs between connected structures,

the connection point may be subjected to a more significant stress than estimated by a steady-state evaluation. In terms of the component temperature, thermal resistance networks are often used to evaluate case and junction temperatures. Once a thermal analysis problem can be expressed, there are usually several ways of solving it, including finite difference, finite element, resistance network, and bulk analysis [1].

Vibration analysis is often used to determine the response of the PWB due to the random oscillating motion of the structure that contains the PWB. While calculating the natural frequency of a PWB, the boundary conditions are assigned on the basis of understanding of the mounting conditions of the board in hardware configurations to conditions such as free, simple, or clamped. Numerically, the natural frequency and first-order response of a rectangular PWB with complete edge supports can be determined using first-order approximations. However, finite element modeling is usually required to evaluate a more diverse and practical range of supports.

The results of stress analysis are often verified and calibrated using experimental results. For example, the natural frequency of a PWB can be experimentally determined using the strain gauge or accelerometer on a PWB, attaching the PWB to a dynamic shaker, and measuring the response of the PWB to a known input.

Reliability Assessment. With the failure sites, stress inputs, and failure models, the reliability of a product is estimated and reported in terms of times to failure of its individual functional units. To define failure, damage metric is established. The damage metric value is augmented as the effects of failure mechanisms degrade a failure site. For fixed duration load events, the augmentation is based on the severity and duration of the event. For example, drop of a handheld device results in damage representative of the height of the drop. For repetitive events, a damage rate is established and the damage metric is updated on the basis of number of repetitive events. For thermal cycling events, the damage rate is defined for each cycle and the damage accumulation is proportional to the number of thermal cycles the product endures. When the damage metric exceeds a threshold value, the failure site is identified as failed and the time to failure for the site is determined

(see **Design of Reliability Tests; Reliability Growth Testing; Mathematics of Risk and Reliability; A Select History; Human Reliability Assessment**).

In general, time-to-failure data is obtained as a distribution for each failure site and failure mechanism. This distribution on time to failure is achieved by using the inputs to the failure models as distributions. In reality, all dimensional and material properties are distributed about a nominal value as a result of the normal variations in manufacturing. The same is true for the environmental loads. PoF-based reliability assessment allows for utilization of these natural variations in the reliability assessment. With the time-to-failure distribution on each site known, reliability can be evaluated in different metrics such as hazard rate, warranty return rate, or mean time to failure.

Sensitivity analysis is used to evaluate the sensitivity of the product life to the application, and define the safe operating region for the desired LCP. Sensitivity analysis involves, for each of the dominant failure mechanisms, identification of the functional relationships of time to failure to geometry, material property, and environmental parameters of interest. Sensitivity analysis can be used to identify the optimal values of accelerated stress loads, based on the sensitivity of the dominant failure mechanisms to the loads.

Outputs

The PoF analysis results can be obtained as output in different ways and can be used for various applications. The results can be as basic as a ranked list of potential failures or as sophisticated as design of life-consumption monitoring (LCM).

Ranked Potential Failures. The PoF methodology output can be obtained as a ranked list of potential failures, with associated potential failure modes, sites, and mechanisms. The ranking is obtained by evaluating the severity and occurrence of various failure mechanisms. The failure mechanisms with a higher ranking are considered riskier than others. Higher risk failure mechanisms are given higher priority when product design is updated, screening conditions are determined, accelerated testing plans are designed, and prognostics and remaining life prediction are conducted.

Design Trade-Offs. PoF analysis can be performed on multiple product design and manufacturing variants to compare their reliability and other attributes to perform trade-off analysis between metrics of interest, such as cost and reliability. The sensitivity analysis in PoF assessment also provides a way to obtain reliability as a function of product attributes. Hence, implementing PoF into the design makes the process of trade-off analysis efficient and effective. Typically, the PoF approach outputs the time to failure and the ranked list of failure mechanisms associated with failure sites. The ranked list allows designers to concentrate on locations and mechanisms that are most likely to cause product failure. The PoF methodology may be used to guide design improvement by identifying the drivers for the dominant failure mechanisms during each life-cycle phase. Design trade-offs can then be evaluated by determining the sensitivity of the dominant degradation mechanisms to the drivers of the mechanisms.

If the reliability of a specific design made by a specific manufacturing process cannot meet the reliability requirements within the cost and lead time constraints, guidance from the PoF analysis can be used to improve the reliability. The options for the trade-offs include using a different material with better thermomechanical properties, improving a current manufacturing process with lower variability, or implementing a new process to reduce or avoid damage to materials during the process, and/or revising a

product's architecture, such as adding or redesigning a heat sink. Since factors like these are inputs to the PoF analysis, the effects of these changes on product reliability can be computed and compared with the original and alternative designs.

Virtual Qualification. Virtual qualification is a methodology for assessing and improving the durability of electronic equipment through the use of validated failure models/simulation tools. Virtual qualification (also called *simulation-assisted reliability assessment*) assesses whether a part or system can meet defined life-cycle requirements based on its materials, geometry, and operating characteristics. The technique involves the application of simulation software to model physical hardware to determine the probability that the system will meet the desired life goals [12–14].

By implementing PoF, virtual qualification can be applied at different design stages and hence move reliability assessment into the design phase [15, 16]. This accelerated product qualification process emphasizes the physical process that produces failures in electronic systems. It allows the design team to consider qualification at the initial stages of design, technology and functional definition, and supplier selection. A flowchart of virtual qualification is shown in Figure 3. This system takes advantage of advances in computer-aided engineering software permitting components and systems to be qualified

Figure 3 Flowchart of virtual qualification

on the basis of analysis of the susceptibility of their designs to failure due to a number of fundamental physical and chemical mechanisms. The reliability assessment tool assesses the candidate and existing package or module designs for reliability in many different environments, using a database of fully validated PoF models. It calculates times to failure for the mechanisms that cause failures and evaluates the effects of different manufacturing processes on reliability by calculating the time to failure as a function of typical manufacturing tolerances and defects. It facilitates the selection of cost-effective test parameters for validating reliability assessment and design and also aids in the selection of components by permitting their virtual qualification [17].

Screening Conditions. Screening conditions of electronic products are often selected from government/military specifications as MIL-STD-883 [18], but screening conditions are arbitrary and not based on understanding of the defects in products to its failure propensity. PoF approach to screening is based on the fact that the stresses and stress magnitudes, which affect the dominant failure mechanisms, are controlled by the levels of defects in a product. The screening conditions are thus determined by the calculation of threshold levels of defects in a product. Below these threshold levels of defects, a product is likely to be reliable. The PoF outputs identify the magnitude of defects that can be allowed to pass the screens. PoF is then used to determine the screening loads and magnitudes to isolate the products that have defects above the threshold level.

Since PoF identifies the correlation between the defect magnitudes and operational life, the failures during in-process testing and screening can be evaluated against the prediction for modes and mechanisms. Thus, PoF method of screening condition development allows for validating the effectiveness of screens and allows its improvement.

Accelerated Test Conditions. Accelerated testing is intended to shorten the normal time to failure of a product due to a specific failure mechanism, generally through application of higher stress levels on a product. The application of increased stresses is usually for the purpose of (a) ruggedizing the design and manufacturing process of the package through systematic step-stress testing and increasing the stress margins by corrective action (reliability enhancement

testing), (b) conducting compressed/accelerated life tests in the laboratory to verify in-service reliability (qualification testing), and (c) eliminating weak or defective specimens from the main population (quality conformance testing). In PoF-based design, the accelerated test formulation is based on an understanding of the failure mechanisms and associated causes. Accelerated testing can be a value-added activity that allows verification of design goals over a short period, thereby achieving faster design modification. However, the value of accelerated tests can be realized only if there is an associated predictive capacity regarding the effect of accelerated tests on failure modes and mechanisms.

The accelerated test conditions can be seen as a corollary to virtual qualification, where the output is provided in the form of a test plan. This test plan will include test stress type(s), stress levels, duration of the test, definitions of failure, expected times of failures, and the site, mode, and mechanism. In addition, if the accelerated tests are meant to be qualification or acceptance tests, then acceptance criteria for such decisions can also be identified in the plan. From a test standpoint, acceleration factors can be established between the anticipated LCP and the set of qualifying tests. Redundant and nonvalue added tests can be eliminated.

Prognostics and Life-Consumption Monitoring Process. Prognostics is a method of evaluating the extent of a product's reliability in terms of product degradation in its life-cycle environment. Determining the impending failure based on actual life-cycle application conditions allows procedures to be developed to mitigate, manage, or maintain the product. To reduce the design margin and to predict life more accurately, an increasing emphasis has been placed on prognosis of remaining useful life of components through physics-based damage models or models based on microstructure and constitutive properties. To assess damage and predict the remaining useful life and to use the entire capability of a given material, it is critical to convey the PoF of the material and the material constitutive properties to the designers involved in selecting materials and sizing components. The results of PoF analysis can be used to help determine what to monitor, where to monitor it, and how to react to the results of monitoring.

LCM is one of the prognostic approaches that assess the life consumption and the remaining life of a

product in its life cycle. The life-consumption process involves continuous or periodic measurement, sensing, recording, and interpretation of physical parameters associated with a system's life-cycle environment to quantify the amount of system degradation [19]. The PoF analysis output for a prognostics and life-cycle monitoring process will include a life-cycle environment and operation monitoring scheme and the failure mechanisms and models that can be used to determine the remaining life of the products.

PoF analysis also provides a basis for performing environmental stress management. Stress management solutions can be evaluated in terms of their effectiveness in reducing harmful loads and increasing the useful life of a product. For example, the response of a circuit card to various levels of vibration could be used to determine the amount of damping required to adequately protect the circuit card. Stress management can also take the form of derating components to reduce their electrical stress levels and increase their times to failure.

Applications of Physics of Failure in Product Life Cycle

PoF methodology and design tools allow reliability engineering to become "proactive" rather than "reactive", and have numerous applications in product design, manufacturing, and support. The PoF methodology and tools have reduced the number of time-consuming and expensive hardware design and test iterations, making it feasible to assess and improve reliability in the conceptual design stage by bringing together the reliability team members in the supply chain before expensive manufacturing commitments are made. Some successful implementations of PoF are discussed in this section.

Virtual Qualification

Virtual qualification of electronic hardware has been used for many years. One of the first documented cases of virtual qualification involved the examination of circuit cards in military radios.

In this case, three circuit cards were modeled in virtual qualification software [20, 21]. The life-cycle load consisted of temperature cycles due to power-on and power-off cycles and vibration load due to mounting in a mobile platform. From the hardware

and the loading conditions, solder interconnects were identified as failure sites and vibration and temperature cycling fatigue were identified as failure mechanisms. Evaluation of the anticipated LCP resulted in a prediction that the product would not meet its defined life-cycle requirement. To verify this result, an accelerated test composed of both temperature cycling and vibration was developed using the virtual qualification model. Test of 10 production units closely match simulation results. On the basis of this finding, the design was modified and reassessed. The modified design was estimated to provide required life and demonstrated to match simulation in test. As a result of the change, the program savings was estimated to be in excess of \$27 million.

In another study, the virtual qualification was used to justify the use of a commercial circuit card assembly (CCA) in place of a ruggedized version. Again, solder interconnects were the identified failure sites and fatigue was the identified failure mechanism. Simulating the life expectancy for the anticipated LCP, the commercial CCA was found to have sufficient life margin for use in the application. Testing verified this simulation. This justification resulted in a savings of \$12 000 per assembly and a program saving of nearly \$1 million for only the first 10 systems [1, 22].

Accelerated Testing

Understanding failure mechanisms is essential for conducting successful accelerated life tests, as advocated in PoF-based reliability prediction methodologies. One of the critical issues is the need for a rational method to quantitatively relate the results of accelerated wear-out tests to in-service reliability, using a scientific acceleration transform. PoF methodology involves quantitative modeling of the expected root-cause failure mechanisms. The output is an estimate of the acceleration factor, which, when multiplied by the accelerated wear-out test data, results in life estimation under life-cycle conditions. The range of accuracy of life estimates in the field can now be related to the scatter in the accelerated test data and to the accuracy in estimating the acceleration factor (which varies with the accuracy of input information and the assumptions built in the failure model) [23]. A successful PoF-based accelerated stress testing program meets product requirements, lowers life-cycle costs, and reduces the time to market for a product.

Guidelines to implement PoF in accelerated wear-out testing have been presented with a case study on an avionics electronic module in an avionics box located in the electronic equipment (EE) bay of a commercial aircraft by Upadhyayula and Dasgupta [23]. This case study focused on the reliability of the surface-mount interconnects, particularly the possibility of enhancing test-time compression by exploring the effects of combined vibration and temperature cycling loads on interconnect fatigue.

The sources of reliability risks under combined life-cycle loads were determined by identifying the potential weak links and dominant failure mechanisms associated with the product. PoF activities include understanding the hardware configuration, determining the product life-cycle loads in the EE bay of the aircraft, and performing an initial PoF assessment of the potential failure modes of the interconnects in the circuit card assembly module. The output ranks the potential weak links expected under life-cycle load combinations.

After all the relevant material properties, part lists, and part drawings were identified and documented, combined thermal and mechanical loads were applied to the assembly, which targets the interested failure mechanism, fatigue of interconnects. The interaction effects between thermal and vibration loads were captured, as shown in Figure 4. Thermomechanical stress analysis was conducted for the temperature history, using viscoplastic finite element method (FEM), to estimate the cyclic thermomechanical stress state in the solder joint. Solder joint life predictions were obtained using the generalized Coffin–Manson damage model; the total damage accumulated was computed using Palmgren–Miner’s hypothesis at each increment, rather than for the entire load history.

The PoF approach to accelerated stress tests includes designing the test loads and the test vehicle, as well as issues related to test setup. Different combinations of loads were applied on different test vehicles. The actual magnitudes of the accelerated stress test loads were determined through a combination of exploratory tests and PoF analysis. Test vehicle characterization was carried out to investigate and calibrate the specimen response to applied thermal and vibration loads. Failure data from over-stress tests was used to compute, using PoF-based timescaling techniques, the accelerated test load levels required to excite wear-out failure mechanisms

in accelerated life tests of the specimen. The specimen response is calibrated over the entire accelerated load range. The characterization, therefore, takes into account the interaction effects between the applied thermal loads and the observed vibration response during the test.

The PoF approach is applied to the accelerated test environment to predict the failure trends by quantifying the rate of damage accumulation as a function of the level of applied stress. Results from this exercise confirm the PoF conjecture that thermal stresses, under combined vibration and thermal environments, can actually inhibit damage caused by vibration fatigue in surface-mount interconnects.

The last step is to verify the reliability assessment. It was confirmed by experimental observations that certain surface-mount interconnects are more vulnerable to repetitive shock vibration (RSV) at room temperature than to a combined application of thermal cycling and vibration loading. The PoF approach captures the complex synergy between vibration and temperature by quantifying the rate of damage accumulation owing to RSV loading as a function of the applied temperature level and the mean stresses experienced due to thermal cycling.

Prognostics and Life-Consumption Monitoring

Prognostics and health management (PHM) is a method that permits reliability assessment of a product or system under its actual application conditions. LCM is a prognostic method to assess the remaining life of a product in its actual life-cycle environment by continuously or periodically measuring the product’s performance parameters and environmental conditions.

One case study of LCM is the remaining life estimation of a test board assembly [19], which was placed under the hood of a 1997 Toyota 4Runner and subjected to normal driving conditions. First, failure mode and mechanism analysis was conducted on the circuit card assembly. Potential failure modes and mechanisms of the circuit board assemblies under certain conditions were identified. Then virtual reliability assessment was conducted by computing the time to failure for the identified failure modes and mechanisms. The temperature and vibration data were used as inputs for stress and damaged models. After temperature and vibration analysis, stress and damage accumulation analysis was conducted to

Figure 4 Assessment of potential failures for combined accelerated test loads [Reproduced from [23]. © John Wiley & Sons, Ltd, 1998.]

estimate the damage accumulation. Palmgren–Miner linear damage accumulation theory was used for the computation, as shown in the following equation.

$$\sum_{i=1}^m \frac{n_i}{N_i} = C \quad (1)$$

where C is a constant. This theory states that where there are m different stress magnitudes in a spectrum, S_i ($1 \leq i \leq m$), each stress contributing $n_i(S_i)$ cycles, then if $N_i(S_i)$ is the number of cycles to failure at a constant stress S_i , failure occurs when the above equation is satisfied.

Then, the remaining life of the circuit card assembly was estimated by subtracting the life consumption of a day from the remaining life of the previous day in an iterative manner, as shown in equation (2)

$$RL_N = RL_{N-1} - DR_N \cdot TL_{N-1} \quad (2)$$

where RL_N is the remaining life at the end of the day N , TL_N is the estimated total life at the end of day N , and DR_N is the damage ratio accumulated at the end of day N . The calculated remaining life and the experimental life are plotted in Figure 5. The remaining life estimation was verified by the experimental monitoring of resistance during the test process. The remaining life was correlated to the resistance increase in the solder joints, and failure was defined as occurrence of 15 resistance increase spikes within a certain time range. It can be seen from the plot that the estimated remaining life value and actual remaining life value are close to each other accidentally.

Acceptance of Physics-of-Failure Methodology

There are many reasons for assessing the reliability of a product. We perform reliability assessment to establish reliability requirements for preliminary design

specifications, planning documents, and requests for proposals; to evaluate the feasibility of designs and manufacturing processes to determine whether the reliability requirements can be met and to make trade-offs, to identify and rank potential failures for corrective actions; to reduce the time needed to gather data for risk assessment; to plan for qualification and test tailoring for root-cause analysis; to assist in warranty, life-cycle cost and product support planning (e.g., maintenance and spares); to address certification and regulatory concerns including safety; and to increase customer confidence.

PoF methodology determines the root cause of failures. It provides a methodology for building in reliability. It assesses the impact of hardware configuration and life-cycle stresses on root-cause failure mechanisms. PoF represents good engineering practices. The PoF approach incorporates reliability into the design process by establishing a scientific basis for evaluating new materials, structures, and technologies. Information to plan tests and screens and to determine electrical and thermomechanical stress margins are identified by the approach.

Estimation of failure mechanisms as the basis of reliability assessment and qualification test design for a system has been accepted by the EIA/JEDEC and SEMATECH, an association of semiconductor manufacturing companies like Intel, IBM, AMD, Infineon,

Figure 5 Plot of estimated remaining life as a function of time [Reproduced from [19]. © IEEE, 2003.]

Phillips, and Texas Instrument.^b Intel's product qualification method [24], which defines environmental, lifetime, and manufacturing use conditions based on target market segments (e.g., desktop, server, and notebook), determines probable stresses with reliability implications, estimate stress levels for modeling, and the modes of testing (e.g., standalone and board mounted), defines accelerated stress conditions necessary to identify failure mechanisms and determines the final stress conditions for testing, follow the PoF principles.

The IEEE 1413 standard [25] identifies the framework for the reliability prediction process for electronic systems (products) and equipment. An IEEE 1413-compliant reliability prediction report must include reasons why the reliability predictions were performed, the intended use of the reliability prediction results, cautions as to how the reliability prediction results must not be used, and where precautions are necessary.

In order to assist the user in the selection and use of a particular reliability prediction methodology complying with IEEE 1413, a list of criteria is provided in IEEE 1413.1 [26]. The criteria consist of questions that concern the inputs, assumptions, and uncertainties associated with each methodology, enabling the risk associated with the methodology to be identified. The PoF-based methodology for reliability prediction fared best in comparison to traditional reliability prediction methods in the assessments performed by industry experts in IEEE 1413.1.

Major organizations in manufacturing superpowers in electronics industry such as China and Korea are using PoF methods in product development and realization. Government of Korea has established centers of excellence to develop and implement PoF-based reliability methods in collaboration with its industrial giants. There is demand for training and implementation assistance for realization of PoF tools in emerging economies such as Turkey, India, and Vietnam.

Summary

To ensure product reliability, an organization must follow certain best practices during the product development process. These practices impact reliability through the selection of materials, product

design, manufacturing, assembly, shipping and handling, operation, maintenance, and repair.

PoF is the preferred methodology to assess product reliability, because it provides the information to rank potential failures, make design trade-offs, plan screens and tests, and conduct prognostics. Currently, the PoF methodology is widely accepted in industry, and professional societies, including the IEEE, EIA/JEDEC, and SEMATECH, have been developing standards to incorporate PoF in the product development and evaluation process.

End Notes

^aIn some cases, the environmental factors experienced by constituents of the product begin before manufacturing e.g., storage of parts (material) far in advance of their use in manufacturing.

Reliability of Consumer Goods with “Fast Turn Around”

Trends

In the past decades, the context of new product development in the consumer goods industry has changed. A study on the trends impacting reliability of technical systems has identified four major trends [1]:

- *Increasingly complex products*

Technology and functionalities become available at a higher pace, and at lower prices. Owing to these lower prices, the technologies and functionalities are introduced in products for the mass market faster. These lower prices for functions also lead to combining more functionality into one single product, e.g., mobile phones today are not just a phone, but they are also a camera, an MP3 player, an agenda, etc. As a result the products become increasingly complex.

- *Strong pressure on time-to-market and fast adoption cycles*

Competition is fierce, and to be able to have a reasonable market share and profit, companies must be the first (or at least one of the first few) to hit the market with new products. Being late often results in competition from cheaper products with similar functionality or equally priced products with increased functionality. At the same time consumers adopt the products faster. For example., it took over 15 years for the VCR to reach commodity price levels and become a standard item in most households, whereas this only took around three years for DVD recorders [2]. Consumer goods with “fast turn around” refer to this type of highly innovative products with even shortened economical life cycle (*see Longevity Risk and Life Annuities*).

- *Increasingly global economy*

The increasingly global economy manifests itself twofold. On the one hand, through the penetration of Internet consumers are much more aware of new products, functions, and features and expect those to be available at their local stores immediately.

Companies can no longer introduce products region by region, thus allowing for local adaptations to meet the varying needs of consumers in the regions. On the other hand, companies also need to utilize the capabilities of subcontractors all over the world to utilize local capabilities in order to achieve optimal product costs. Value chains are disintegrating and development activities are outsourced globally.

- *Decreasing tolerance of consumers for quality and reliability problems*

Although most people do understand the service a product offers, many do not understand (and therefore do not accept) the complexity of the underlying systems. People see, for example, a mobile phone as the functional equivalent of an old wired phone without realizing that complex systems are required to allow the use of these products. At the same time there is a trend of extended warranty periods (*see Imprecise Reliability*) and higher coverage, which allows consumers to return products for a wider range of reasons [3]. For example, in the United States, many retailers have a “no questions asked” return policy and in the European Union consumer rights are increasing and warranty has to be granted in certain cases even outside the product specification [4].

Trying to cope with these four trends in product development is an increasing challenge, especially for highly reliable and innovative products. Many businesses in the consumer electronics industry in the western world have chosen a strategy to bring fundamentally new products to the market with a much higher frequency than before (fast turn around of products). For these products there this will result in two major types of uncertainty [5]:

- Market uncertainty (*see Dynamic Financial Analysis*): the difficulty of potential customers to articulate their needs and thus uncertainty about the market opportunities.
- Technology uncertainty (*see Reliability Optimization*): the difficulty in translating technological advancements into product features and benefits for the customer.

Modern product creation processes require methods and tools to structurally manage these uncertainties during product creation. The following research question naturally arises: To what extent can the commonly used quality and reliability methods and

tools be applied to manage market and technology uncertainty in modern product creation processes?

In the following section, a number of commonly used quality and reliability methods and tools are reviewed on their ability to deal with especially these uncertainties in new product development projects.

Applicability of Quality and Reliability Methods and Tools

Traditional quality and reliability management (*see Reliability Growth Testing*) approaches, starting with the philosophies of Deming [6], Juran [7], and Crosby [8], and building upon those by many authors since then (e.g., Besterfield [9], Chase [10], and Evans and Lindsay [11]), do start from the customer perspective: achieving customer satisfaction through identifying the customer needs and highly effective process improvements. However, these approaches often treat customer needs as stable, and they have rather lengthy processes for data collection and improvement to ensure high quality and reliability. For consumer goods with fast turn around, the consumer needs are highly uncertain, so they cannot be treated as stable and further insight needs are needed during the course of the project. As a result, methods and tools like design for Six Sigma (*see Operational Risk Development*) [12] and robust design [13], which are commonly used, do not work for these products. The same holds for methods that are commonly used in the area of manufacturing to guarantee high product quality at zero hour, such as design of experiments (DOE) and statistical process control (SPC) [14], as well as several test strategies, including accelerated tests [15]. Other methods such as quality function deployment (QFD) [16] have difficulties in dealing with the increasing technology uncertainty [17], as well as market uncertainty [18, 19]. Risk management is one of the more general tools aimed at addressing a variety of risks during new product development projects [20–23]. However, during risk assessments and failure mode and effect analysis (FMEA) (*see Human Reliability Assessment; Probabilistic Risk Assessment*) in projects with higher uncertainties, many potential problems are consciously or unconsciously ignored under strong time-to-market pressure [19]. In addition, quantitative risk assessment methods require

the deployment of the best available information to understand the effects of the identified potential risks. However, owing to the increasing market and technology uncertainties during the creation of consumer goods with fast turn around, the required information is often unavailable or incomplete. Therefore, these tools will no longer be effective for consumer goods with fast turn around. Moreover, the traditional processes for data collection about customer feedback take too much time [24, 25], and do not fit within the tight schedules of the projects in this sector.

Therefore, it can be concluded that, owing to the increasing market as well as technology uncertainties, it is impossible to make accurate prediction and to use maturity measurement techniques during product development. It is also impossible to collect sufficient appropriate data for analysis and improvement prior to market introduction under the strong pressure on time to market. As a result, the commonly known approaches are not applicable to deal with the identified uncertainties in the context of consumer goods with fast turn around.

Reliability in an Innovative Context

Reliability is defined as “the probability that a system will perform its intended function for a specific period of time under a given set of conditions [26]”. As discussed in the previous section, the commonly used quality and reliability methods and tools are incapable of dealing with uncertainties embedded in the development. Given the definition of reliability, this has a number of implications:

- To be competitive, companies introduce new technologies and features into their products early, even though these may not have been proved as mature, leading to higher technical uncertainties on the feasibility of the product specification.
- Globalization and fast adoption leads to a wider range of consumers buying and using the products in a wider variety of environments. As products get more functions, there are also more applications the products can be used in, and often more connectivity options. It is much more difficult to predict consumer expectations with all these parameters, leading to higher uncertainties on the specification and its coverage of expectations.

Product reliability is usually measured by the number of products returned by dissatisfied consumers. Currently many companies in the consumer goods industry are facing an increasing number of product returns for nontechnical reasons, as recent studies have shown [26]. These studies show that around half of the returned products are technically fully functioning according to the specification: the most important reasons for consumers to return a product are that it does not meet their expectation, or that they are not able to get it working [27]. In service centers or repair workshops the products are analyzed to establish the root cause of the problem, but as there is no technical failure, this results in a growing number of “failure not found” classifications [26].

Most companies execute tests during product development and manufacturing to find problems in the product reliability prior to market introduction. These tests are under pressure for a number of reasons. First of all, reliability tests do take time, and are often on the critical path of the project schedule. Owing to the ever decreasing time-to-market, project teams may skip tests to meet the deadline [28]. Secondly, tests do not address all potential problems with the product as project teams tend to overlook the uncertainties in the project. As a result, consumers complain on products in the market for reasons that had not been identified during the product development project. Thirdly, as the variation in consumers, products, applications, and environments are increasing, it is impossible to test all combinations of these variations within the limited time available. As a result, products are released to the market with an unknown reliability level.

In summary, under the four trends discussed earlier, companies have to deal with products entering the market with an unknown reliability level, and it can be expected that a number of products will be returned as they are not fulfilling the consumer’s expectation, although technically these products are according to the specifications.

Managing Reliability in an Innovative Context

As the commonly known approaches to ensure high reliability prior to market introduction are no longer applicable for consumer goods with fast turn around,

other approaches will have to be applied. Managing reliability in new product development projects covers the following aspects: target setting and prediction, maturity measurement during development, and improvement (prevention).

Owing to the uncertainties, it is impossible to use accurate prediction and maturity measurement techniques during new product development. Therefore, the appropriate approach is to create fast learning cycles for both technical and nontechnical risks. This means that risk-driven test strategies need to be developed, which include tests with consumers to reduce the market uncertainties, as well as functional tests to reduce the technological uncertainties. These test strategies include a series of tests, starting as early as possible (using paper concepts, simulations, or early prototypes). Owing to the limited time available in projects (due to the time-to-market pressure), it will be impossible to get large amounts of data from these tests. The tests should therefore focus on increasing the quality of the data. This can be done by collecting more information from a limited number of tests. For example, when tests are performed with consumers, the main factors influencing the reliability should be included in the tests, such as consumer types, types of environment, and types of tasks consumers will execute with the product. High contrast consumer testing (HCCT) has proved to be a powerful method to set up a limited set of tests that generates rich information [29] that can be used by product development teams to improve the design such that the problems encountered by the participants in the test can be prevented.

Example 1^a: A multinational consumer electronics manufacturer would like to introduce a new ironer to the market. The new ironer consisted of a digital user interface comparing with traditional ironer and the development time was expected to be shortened. In the early development process, the development team realized that, given the uncertain consumer use of the user interface, it was necessary to collect as early as possible consumer use information by testing a number of early prototypes with real consumers. HCCT was applied there and the development team was able to very quickly identify a number of product flaws, which was not possible to be identified using traditional quality and reliability risk assessment methods, and necessary corrective actions were implemented accordingly.

Conclusion

Companies developing consumer goods with fast turn around are faced with increased levels of uncertainty in both market and technology. Commonly available methods and tools for product quality and reliability are not applicable in this context. As a result, there is an explosion in the number of consumers returning products that are fully working according to the specifications. To prevent these complaints, companies will need to change their test strategies. These strategies should be consumer oriented and focus on a limited number of tests providing data of a higher quality, and that can be used to improve the design prior to market introduction.

End Notes

^aName and details of the manufacturer cannot be disclosed here owing to reasons of confidentiality. Full details, however, are known to the authors.

Reliability of Large Systems

Many technical systems belong to the class of complex systems as a result of the large number of components they are built of and their complicated operating processes. As a rule, these are series systems composed of a large number of components (*see Reliability Optimization*). Sometimes the series systems have either components or subsystems reserved and then they become parallel-series or series-parallel reliability structures (*see Multi-state Systems; Game Theoretic Methods*). We find large series systems, for instance, in transportation of water, gas, oil, and various chemical substances through pipes. Large systems of these kinds are also used in electrical energy distribution. A city bus transportation system composed of a number of communication lines each serviced by one bus may be a model series system, if we treat it as not failed, when all its lines are able to transport passengers. If the communication lines have several buses at their disposal, we may consider it as either a parallel-series system or an “ m out of n ” system. The simplest example of a parallel system or an “ m out of n ” system may be an electrical cable composed of a number of wires, which are its basic components, whereas the transmitting electrical network may be either a parallel-series system or an “ m out of n ” series system. Large systems of these types are also used in telecommunication, in rope transportation, and in transport using belt conveyors and elevators. Rope transportation systems like port elevators and ship-rope elevators used in shipyards during ship docking are model examples of series-parallel and parallel-series systems.

In the case of large systems, the determination of the exact reliability functions of the systems leads us to complicated formulae that are often useless for reliability practitioners. One of the important techniques in this situation is the asymptotic approach to system reliability evaluation (*see Bayesian Statistics in Quantitative Risk Assessment*). In this approach, instead of the preliminary complex formula for the system reliability function, after assuming that the number of system components tends to infinity and finding the limit reliability of the system, we obtain its simplified form.

The mathematical methods used in the asymptotic approach to the system reliability analysis of large systems are based on limit theorems on order statistics distributions, considered in very wide literature, for instance, in [1–4]. These theorems have generated the investigation concerned with limit reliability functions of the systems composed of two-state components. The main and fundamental results on this subject that determine the three-element classes of limit reliability functions for homogeneous series systems and for homogeneous parallel systems have been established by Gnidenko [5]. These results are also presented, sometimes with different proofs, for instance, in subsequent works [6, 7]. The generalizations of these results for homogeneous “ m out of n ” systems have been formulated and proved by Smirnow [8], where the seven-element class of possible limit reliability functions for these systems has been fixed. As it has been done for homogeneous series and parallel systems, classes of limit reliability functions have been fixed by Chernoff and Teicher [9] for homogeneous series-parallel and parallel-series systems. Their results were concerned with so-called quadratic systems only. They have fixed limit reliability functions for the homogeneous series-parallel systems with the number of series subsystems equal to the number of components in these subsystems, and for the homogeneous parallel-series systems with the number of parallel subsystems equal to the number of components in these subsystems. The generalizations of these results for nonquadratic and nonhomogeneous series-parallel and parallel-series systems are formulated and proved in [7].

All the results so far described have been obtained under the linear normalization of the system lifetimes. This article contains exemplary results described above for homogeneous series and parallel systems and comments on newest generalizations recently presented in [10].

Reliability of Two-State Systems

We assume that

$$E_i, i = 1, 2, \dots, n, \quad n \in N \quad (1)$$

are two-state components of the system having reliability functions

$$R_i(t) = P(T_i > t), \quad t \in (-\infty, \infty) \quad (2)$$

where

$$T_i, \quad i = 1, 2, \dots, n$$

are independent random variables representing the lifetimes of components E_i with distribution functions (see **Multistate Systems; Imprecise Reliability**)

$$F_i(t) = P(T_i \leq t), \quad t \in (-\infty, \infty) \quad (3)$$

The simplest two-state reliability structures are series and parallel systems. We define these systems first.

We call a two-state system series if it is not failed, if and only if all its components are not failed. It means that the series system lifetime T is given by

$$T = \min_{1 \leq i \leq n} \{T_i\} \quad (4)$$

and therefore its reliability function is given by

$$\bar{R}_n(t) = \prod_{i=1}^n R_i(t), \quad t \in (-\infty, \infty) \quad (5)$$

The scheme of a series system is given in Figure 1.

We call a two-state system parallel if it is failed, if and only if all its components are failed. It means that the parallel system lifetime T is given by

$$T = \max_{1 \leq i \leq n} \{T_i\} \quad (6)$$

and therefore its reliability function is given by

$$R_n(t) = 1 - \prod_{i=1}^n F_i(t), \quad t \in (-\infty, \infty) \quad (7)$$

The scheme of a parallel system is given in Figure 2.

We call a two-state system homogeneous if its component lifetimes have an identical distribution function $F(t)$, i.e., if its components have the same reliability function $R(t) = 1 - F(t)$, $t \in (-\infty, \infty)$.

The above definition and equations (5)–(7) result in the simplified formulae for the reliability functions of the homogeneous systems as follows:

Figure 1 The scheme of a series system

Figure 2 The scheme of a parallel system

- for a series system

$$\bar{R}_n(t) = [R(t)]^n, \quad t \in (-\infty, \infty) \quad (8)$$

- for a parallel system

$$R_n(t) = 1 - [F(t)]^n, \quad t \in (-\infty, \infty) \quad (9)$$

Asymptotic Approach to System Reliability

The asymptotic approach (see **Repair, Inspection, and Replacement Models; Extreme Values in Reliability**) to the reliability of two-state systems depends on the investigation of limit distributions of a standardized random variable

$$\frac{(T - b_n)}{a_n} \quad (10)$$

where T is the lifetime of a system and $a_n > 0$ and $b_n \in (-\infty, \infty)$ are suitably chosen numbers called *normalizing constants*.

Since

$$\begin{aligned} P((T - b_n)/a_n > t) &= P(T > a_n t + b_n) \\ &= R_n(a_n t + b_n) \end{aligned} \quad (11)$$

where $R_n(t)$ is a reliability function of a system composed of n components, the following definition becomes natural.

Definition 1 We call a reliability function $\mathfrak{R}(t)$ the limit reliability function of a system having a reliability function $R_n(t)$ if there exist normalizing constants $a_n > 0$, $b_n \in (-\infty, \infty)$ such that

$$\lim_{n \rightarrow \infty} R_n(a_n t + b_n) = \mathfrak{R}(t) \text{ for } t \in C_{\mathfrak{R}} \quad (12)$$

where $C_{\mathfrak{R}}$ is the set of continuity points of $\mathfrak{R}(t)$.

Thus, if the asymptotic reliability function $\mathfrak{R}(t)$ of a system is known, then for sufficiently large n , the approximate formula

$$\mathbf{R}_n(t) \cong \mathfrak{R}((t - b_n)/a_n), \quad t \in (-\infty, \infty) \quad (13)$$

may be used instead of the system exact reliability function $\mathbf{R}_n(t)$.

Reliability of Large Two-State Series Systems

The investigations of limit reliability functions of homogeneous two-state series systems are based on the following auxiliary theorem [5–7].

Lemma 1 *If*

- (i) $\bar{\mathfrak{R}}(t) = \exp[-\bar{V}(t)]$ is a nondegenerate reliability function,
- (ii) $\bar{\mathbf{R}}_n(t)$ is the reliability function of a homogeneous two-state series system defined by equation (8),
- (iii) $a_n > 0, b_n \in (-\infty, \infty)$,

then

$$\lim_{n \rightarrow \infty} \bar{\mathbf{R}}_n(a_n t + b_n) = \bar{\mathfrak{R}}(t) \text{ for } t \in C_{\bar{\mathfrak{R}}} \quad (14)$$

if and only if

$$\lim_{n \rightarrow \infty} nF(a_n t + b_n) = \bar{V}(t) \text{ for } t \in C_{\bar{V}} \quad (15)$$

Lemma 1 is an essential tool in finding limit reliability functions of two-state series systems. It is also the basis for fixing the class of all possible limit reliability functions of these systems. This class is determined by the following theorem [5–7].

Theorem 1 *The only nondegenerate limit reliability functions of the homogeneous two-state series system are*

$$\begin{aligned} \bar{\mathfrak{R}}_1(t) &= \exp[-(-t)^{-\alpha}] \text{ for } t < 0, \bar{\mathfrak{R}}_1(t) \\ &= 0 \text{ for } t \geq 0, \alpha > 0 \end{aligned} \quad (16)$$

$$\begin{aligned} \bar{\mathfrak{R}}_2(t) &= 1 \text{ for } t < 0, \bar{\mathfrak{R}}_2(t) \\ &= \exp[-t^\alpha] \text{ for } t \geq 0, \alpha > 0 \end{aligned} \quad (17)$$

$$\bar{\mathfrak{R}}_3(t) = \exp[-\exp[t]] \text{ for } t \in (-\infty, \infty) \quad (18)$$

Reliability of Large Two-State Parallel Systems

The class of limit reliability functions for homogeneous two-state parallel systems may be determined on the basis of the following auxiliary theorem [5–7].

Lemma 2 *If*

- (i) $\mathfrak{R}(t) = 1 - \exp[-V(t)]$ is a nondegenerate reliability function,
- (ii) $\mathbf{R}_n(t)$ is the reliability function of a homogeneous two-state parallel system defined by equation (9), $a_n > 0, b_n \in (-\infty, \infty)$,

then

$$\lim_{n \rightarrow \infty} \mathbf{R}_n(a_n t + b_n) = \mathfrak{R}(t) \text{ for } t \in C_{\mathfrak{R}} \quad (19)$$

if and only if

$$\lim_{n \rightarrow \infty} nR(a_n t + b_n) = V(t) \text{ for } t \in C_V \quad (20)$$

By applying Lemma 2, it is possible to fix the class of limit reliability functions for homogeneous two-state parallel systems. However, it is easier to obtain this result using the duality property of parallel and series systems expressed in the relationship

$$\mathbf{R}_n(t) = 1 - \bar{\mathbf{R}}_n(-t) \text{ for } t \in (-\infty, \infty) \quad (21)$$

which results in the following Lemma ([5–7, 10]).

Lemma 3 *If $\bar{\mathfrak{R}}(t)$ is the limit reliability function of a homogeneous two-state series system with reliability functions of particular components $\bar{R}(t)$, then*

$$\mathfrak{R}(t) = 1 - \bar{\mathfrak{R}}(-t) \text{ for } t \in C_{\bar{\mathfrak{R}}} \quad (22)$$

is the limit reliability function of a homogeneous two-state parallel system with reliability functions of particular components

$$R(t) = 1 - \bar{R}(-t) \text{ for } t \in C_{\bar{R}} \quad (23)$$

At the same time, if (a_n, b_n) is a pair of normalizing constants in the first case, then $(a_n, -b_n)$ is such a pair in the second case.

The application of Lemma 3 and Theorem 1 yields the following result [5–7].

Theorem 2 *The only nondegenerate limit reliability functions of the homogeneous parallel system are*

$$\begin{aligned} \mathfrak{R}_1(t) &= 1 \text{ for } t \leq 0, \mathfrak{R}_1(t) \\ &= 1 - \exp[-t^{-\alpha}] \text{ for } t > 0, \alpha > 0 \end{aligned} \quad (24)$$

$$\begin{aligned} \mathfrak{R}_2(t) &= 1 - \exp[-(-t)^\alpha] \text{ for } t < 0, \mathfrak{R}_2(t) \\ &= 0 \text{ for } t \geq 0, \alpha > 0 \end{aligned} \quad (25)$$

$$\mathfrak{R}_3(t) = 1 - \exp[-\exp[-t]] \text{ for } t \in (-\infty, \infty) \quad (26)$$

Using Lemma 2, it is possible to prove the following fact [10].

Corollary 1 *If components of the homogeneous two-state parallel system have Weibull reliability functions*

$$R(t) = 1 \text{ for } t < 0, R(t) = \exp[-\beta t^\alpha] \text{ for } t \geq 0, \alpha > 0, \beta > 0 \quad (27)$$

and

$$a_n = b_n/(\alpha \log n), b_n = (\log n/\beta)^{1/\alpha} \quad (28)$$

then

$$\mathfrak{R}_3(t) = 1 - \exp[-\exp[-t]], t \in (-\infty, \infty) \quad (29)$$

is its limit reliability function.

Example 1 (A steel rope, durability) Let us consider a steel rope composed of 36 strands used in ship-rope elevator and assume that it has not failed if at least one of its strands is not broken. Under this assumption we may consider the rope as a homogeneous parallel system composed of $n = 36$ basic components. The cross section of the considered rope is presented in Figure 3.

Further, assuming that the strands have Weibull reliability functions with parameters

$$\alpha = 2, \beta = (7.07)^{-6} \quad (30)$$

by equation (9), the rope's exact reliability function takes the form

$$R_{36}(t) = 1 \text{ for } t < 0, R_{36}(t) = 1 - [1 - \exp[-(7.07)^{-6}t^2]]^{36} \text{ for } t \geq 0 \quad (31)$$

Figure 3 The cross-section of the steel rope

Thus, according to Corollary 1, assuming

$$a_n = (7.07)^3/(2\sqrt{\log 36}), b_n = (7.07)^3\sqrt{\log 36} \quad (32)$$

and applying equation (13), we arrive at the approximate formula for the rope reliability function of the form

$$R_{36}(t) \cong \mathfrak{R}_3((t - b_n)/a_n) = 1 - \exp[-\exp[-0.01071t + 7.167]] \text{ for } t \in (-\infty, \infty) \quad (33)$$

The mean value of the rope lifetime T and its standard deviation, in months, calculated on the basis of the above approximate result and according to the formulae

$$E[T] = Ca_n + b_n, \sigma = \pi a_n/\sqrt{6} \quad (34)$$

where $C \cong 0.5772$ is Euler's constant, are, respectively,

$$E[T] \cong 723, \sigma \cong 120 \quad (35)$$

The values of the exact and approximate reliability functions of the rope are presented in Table 1 and graphically in Figure 4. The differences between them are not large, which means that the mistakes in replacing the exact rope reliability function by its approximate form are practically not significant.

Table 1 The values of the exact and approximate reliability functions of the steel rope

t	$R_{36}(t)$	$\mathfrak{R}_3\left(\frac{t-b_n}{a_n}\right)$	$\Delta = R_{36} - \mathfrak{R}_3$
0	1.000	1.000	0.000

Conclusions

Generalizations of the results on limit reliability functions of two-state homogeneous systems for these and other two-state systems, in case they are nonhomogeneous, are mostly given in [7, 10]. More general and practically important complex systems composed of multistate and degrading in time components are considered in wide literature, for instance, in [11]. An especially important role that they play in the evaluation of technical systems reliability and safety and their operating process effectiveness is described in [10] for large multistate systems with degrading components. The most important results regarding generalizations of the results on limit reliability functions of two-state systems dependent on transferring them to series, parallel, “ m out of n ”, series-parallel and parallel-series multistate systems with degrading components are given in [10]. Some practical applications of the asymptotic approach to the reliability evaluation of various technical systems are available in [10] as well.

The results concerned with the asymptotic approach to system reliability analysis have become the basis for the investigation concerned with domains of attraction for the limit reliability functions of the considered systems. In a natural way, they have led to investigation of the speed of convergence of the system reliability function sequences to their limit

reliability functions. These results have also initiated the investigation of limit reliability functions of “ m out of n ”-series, series-“ m out of n ” systems, systems with hierarchical reliability structures and systems varying in time, their structures and components, reliability functions, as well as investigations on the problems of the system reliability improvement and optimization described briefly in [10].

Reliability Optimization

The design of new products involves the specification of performance requirements, the evaluation and selection, or possibly development, of components to perform clearly defined functions and the determination of a system-level architecture (*see Systems Reliability*). Once a decision has been made to produce a new product, detailed engineering specifications are determined to prescribe minimum levels of reliability, maximum weight, maximum volume, etc. If the design is to be produced economically or within some specified budget, numerous design alternatives must be considered, resulting in a difficult optimization problem.

Reliability Optimization Problems

There are different classes of reliability optimization problems depending on the selected objective function and decision variables. For single objective problems, the primary types of problems are redundancy allocation problem, reliability allocation problem, and reliability–redundancy allocation problem. Kuo *et al.* [1] provides an excellent overview and summary of reliability optimization research.

Redundancy Allocation Problem

The most widely studied reliability optimization problem is the redundancy allocation problem (*see Multistate Systems*). For systems designed using off-the-shelf component types, with fixed cost, reliability, and weight characteristics, system design becomes a combinatorial optimization problem. For each required function identified within the design process, there are often many different component types available with different levels of cost, reliability, weight, and other properties. The problem is, then, to select the optimal combination of parts and levels of redundancy to collectively meet reliability, weight, and other constraints at a minimum cost, or alternatively, to maximize reliability, given constraints on various system properties.

For this problem, there are m_i discrete component choices available for each subsystem ($i = 1, \dots, s$). Figure 1 presents a typical example of a series system with k -out-of- n subsystem reliabilities. If k is one for

each subsystem, then this is a series–parallel system. For each subsystem, a minimum of k_i components must be chosen from among the m_i available choices (with an unlimited supply available for each of the m_i components). It may become necessary to place additional components in parallel to achieve the reliability requirement. Additionally, it may be advantageous to use more levels of redundancy ($> k_i$) of a lower reliability component as an alternative to using a more reliable, but more costly component. As a result, there is a large number of possible solutions even for relatively small problems.

The redundancy allocation problem for a series–parallel system, as depicted in Figure 1, can be formulated to maximize reliability (equation (1)) or to minimize cost (equation (2)), given various constraints. Typical formulations are as follows:

$$\max \quad R(\mathbf{x}) = \prod_{i=1}^s R_i(\mathbf{x}_i | k_i) \quad (1)$$

$$\begin{aligned} \text{subject to:} \quad & \sum_{i=1}^s C_i(\mathbf{x}_i) \leq C_o \\ & \sum_{i=1}^s W_i(\mathbf{x}_i) \leq W_o \\ & k_i \leq \sum_{j=1}^{m_i} x_{ij} \leq n_{\max,i} \quad \forall i = 1, 2, \dots, s \\ & x_{ij} \in \{0, 1, 2, \dots\} \end{aligned}$$

$$\min \quad \sum_{i=1}^s C_i(\mathbf{x}_i) \quad (2)$$

$$\begin{aligned} \text{subject to:} \quad & \prod_{i=1}^s R_i(\mathbf{x}_i | k_i) \geq R_o \\ & \sum_{i=1}^s W_i(\mathbf{x}_i) \leq W_o \\ & k_i \leq \sum_{j=1}^{m_i} x_{ij} \leq n_{\max,i} \quad \forall i = 1, 2, \dots, s \\ & x_{ij} \in \{0, 1, 2, \dots\} \end{aligned}$$

where

R_o : minimum system reliability

C_o : maximum system cost

W_o : maximum system weight

Figure 1 Series-parallel system

s : number of subsystems

$\mathbf{x}_i$: $(x_{i1}, x_{i2}, \dots, x_{i,m_i})$

x_{ij} : number of the j th component used in subsystem i

$n_{max,i}$: maximum number of components used in subsystem i (specified)

$R_i(\mathbf{x}_i|k_i)$: reliability of subsystem i , given k_i

k_i : minimum number of components required for subsystem i to operate

$C_i(\mathbf{x}_i)$: total cost of subsystem i

$W_i(\mathbf{x}_i)$: total weight of subsystem i .

The redundancy allocation problem for series-parallel systems has proved to be difficult. Chern [2] showed that the problem is NP hard. Many different optimization approaches have been used to determine optimal or “very good” solutions. Previous research involving this problem can be classified on the basis of the solution approach as (a) dynamic programming (see **Repair, Inspection, and Replacement Models**), (b) integer programming, (c) mixed integer and nonlinear programming, or (c) metaheuristics.

Bellman [3] and Bellman and Dreyfuss [4, 5] showed that an optimal solution to the redundancy allocation problem could be found using dynamic programming if there was only one component choice for each subsystem. In the original Bellman formulation, the objective was to maximize reliability given a single cost constraint. For each subsystem, the problem was then to identify the optimal levels of redundancy. A well-known disadvantage of dynamic programming formulations is the inability to handle multiple constraints efficiently.

Fyffe *et al.* [6] also used a dynamic programming approach and solved a more difficult design problem.

They considered a system with 14 subsystems and constraints on both cost and weight. For each subsystem in the Fyffe formulation, there are three or four different component choices, each with different reliability, cost, and weight. To accommodate multiple constraints within a dynamic programming formulation, a Lagrangian multiplier is used for the weight constraint within the objective function. The equivalent dynamic programming formulation of the problem is as follows. Their approach to constraint satisfaction uses Lagrangian relaxation. The objective function incorporates the original objective function (system reliability), the constrained system weight and λ , a Lagrangian multiplier.

$$\begin{aligned} \max \quad & \left[\prod_{i=1}^s R_i(\mathbf{x}_i|k_i = 1) \right] e^{-\lambda \sum_{i=1}^s W_i(\mathbf{x}_i)} \\ \text{subject to} \quad & \sum_{i=1}^s C_i(\mathbf{x}_i) \leq C_0 \end{aligned} \quad (3)$$

The dynamic programming recursion formulas are as follows, where the final solution is found at $f_s(C_0)$ for the optimal value of λ .

$$f_1(\alpha) = \max_{\mathbf{x}_1: C_1(\mathbf{x}_1) \leq \alpha} \{ R_1(\mathbf{x}_1|k_1) e^{-\lambda W(\mathbf{x}_1)} \} \quad (4)$$

$$\begin{aligned} f_i(\beta) = \max_{\mathbf{x}_i: \sum C_i(\mathbf{x}_i) \leq \beta} \\ \times \{ R_i(\mathbf{x}_i|k_i) e^{-\lambda W(\mathbf{x}_i)} f_{i-1}(\beta - C_i(\mathbf{x}_i)) \} \\ \text{for } i = 2, \dots, s \end{aligned} \quad (5)$$

To use the Fyffe *et al.* [6] dynamic programming algorithm, it is necessary to assume a Lagrangian multiplier value (λ) and then successively solve recursion formulas starting with the function $f_1(\alpha)$, $f_2(\beta)$ and continuing on until $f_{s-1}(\beta)$. Then, $f_s(C_0)$ is the optimal solution for that particular λ . If $\sum W_i(\mathbf{x}_i) = W_0$ or $\sum C_i(\mathbf{x}_i) = C_0$, and $\sum W_i(\mathbf{x}_i) \leq W_0$, then this is the final solution. If not, then λ must be incrementally changed, and the recursion formulas repeated, until one of the equality conditions is met and the final solution is found. In practice, the equality constraints may not be exactly met because of the integer constraints on the number of components. In this case, it is not always possible to determine the optimal solution.

Nakagawa and Miyazaki [7] showed that the use of a Lagrangian multiplier with dynamic programming can be inefficient. Instead of using Lagrangian

multipliers, they deployed a surrogate constraint combining the cost and weight constraints into one. It was then necessary to solve a series of problem iterations with different surrogate multipliers. A heuristic was presented to successively update the surrogate multipliers. Additionally, a stopping criteria was provided to identify cases when the Nakagawa and Miyazaki (N&M) algorithm would not lead to an optimal solution. The algorithm was demonstrated by solving 33 variations of the Fyffe problem with different weight constraints ($W_0 = 159-191$). Of the 33 problems, the N&M algorithm produced optimal solutions to 30 of these problems. In the other cases, the final solution was not feasible, although feasible solutions to the problem do exist. In general, the N&M algorithm worked best when one of the two constraints had slack.

Many variations of the problem can be transformed into equivalent integer programming problems. This was originally demonstrated and proved by Ghare and Taylor [8], who used a branch-and-bound approach to solve randomly generated redundancy allocation problems with 30 subsystems with 15 constraints, and 99 subsystems with 10 constraints. In all cases, Ghare and Taylor assumed that there was only one component choice for each subsystem.

Bulfin and Liu [9] also used an integer programming approach to the redundancy allocation problem. One heuristic and two exact algorithms were proposed, depending on the problem structure. They formulated the problem as a knapsack problem (KP) and used a surrogate constraints approach analogous to that of Nakagawa and Miyazaki [7]. The surrogate multipliers were approximated as the optimal Lagrangian multipliers as found by subgradient optimization [10]. Bulfin and Liu determined solutions to all 33 problems investigated by Nakagawa and Miyazaki, as well as other examples, with good results.

Other examples of integer programming solutions to the redundancy allocation problem were presented by Misra and Sharma [11], Gen *et al.* [12, 13]. Misra and Sharma presented a very fast and useful algorithm to solve integer programming problems formulated like that of Ghare and Taylor [8]. Gen *et al.* formulated the problem as a multiobjective decision-making problem with distinct goals for reliability, cost, and weight.

The application of metaheuristics in recent years has resulted in impressive results. Coit and Smith [14]

applied genetic algorithms (GA). Their work and that of Levitin *et al.* [15] were among the first papers that considered component mixing for redundancy allocation problem (RAP). Component mixing involves the use of functionally equivalent components within the same subsystem to provide redundancy (e.g., a mechanical gyroscope providing redundancy for an electronic gyroscope in an airplane). Later, Kulturel-Konak *et al.* [16] presented the application of Tabu Search, and Liang and Smith [17] presented the Ant Colony Optimization. The advantage of metaheuristics is that they usually yield good results in a relatively short time. The drawbacks are that they cannot guarantee global optimality, not always yield repeatable results, and generally require customized versions for particular problems.

Most of the RAP solution methodologies only allow active redundancy. Coit [18] presented an integer programming approach to solve the problem with cold-standby redundancy. Later, Coit [19] proposed an approach that allowed for a choice of active or cold-standby redundancy.

Reliability Allocation Problem

The reliability allocation problem is fundamentally different. For this problem, the system structure is fixed and the component reliability values are bounded continuous decision variables. For this problem, there is no general restriction on the system structure. Figure 2 shows an example of a general system. Component cost and other parameters are generally expressed as mathematical functions of the component reliability. Increasing the component reliability (and thus, the system reliability) can therefore increase the cost, weight, and other factors that should be considered when designing a system.

Figure 2 Example of a general system

For the reliability allocation problem, the general mathematical formulation can be represented as

$$\begin{aligned} & \max_{\mathbf{r}} R(\mathbf{r}) \\ & \text{subject to:} \\ & g_p(\mathbf{r}) \leq b_p : \forall p \in \{1, 2, \dots\} \\ & r_i^l \leq r_i \leq r_i^u : \forall i \in \{1, 2, \dots\} \end{aligned} \quad (6)$$

where

$R(\mathbf{r})$: system reliability as a function of $\mathbf{r}$

$\mathbf{r}$: (r_1, r_2, r_3)

r_i : reliability of the component i

r_i^l, r_i^u : lower and upper bound for r_i

$g_p(\mathbf{r})$: p th system performance measure (cost, weight, etc.)

b_p : p th constraint limit (cost budget, maximum allowable weight, etc.).

Since the only decision variables are continuous, forms of nonlinear programming can be used to determine solutions [1]. To accommodate the constraints, Lagrangian multipliers, or penalty, or barrier functions are used. Successful solutions to this problem were developed by Hwang *et al.* [20] on the basis of sequential unconstrained minimization techniques (SUMT) and Kuo *et al.* [21] who used the branch-and-bound method.

Reliability–Redundancy Allocation Problem

The reliability–redundancy allocation problem is the most general problem formulation. The system is composed of one or more “subsystems”. Each subsystem has x_i components in parallel with reliability of r_i and the decision is how to optimally allocate redundancy and reliability to the components of each subsystem so that the overall reliability of the system is maximized. In general, subsystems can be in any arrangement, as depicted in Figure 2.

Increasing the reliability and redundancy levels can increase the cost, weight, and other factors that should be considered when designing a system. The general mathematical formulation can be represented as

$$\begin{aligned} & \max_{\{\mathbf{r}, \mathbf{x}\}} R(\mathbf{r}, \mathbf{x}) \\ & \text{subject to} \\ & g_p(\mathbf{r}, \mathbf{x}) \leq b_p : \forall p \in \{1, 2, \dots\} \\ & l_i \leq x_i \leq u_i : \forall i \in \{1, 2, \dots, s\} \\ & r_i^l \leq r_i \leq r_i^u : \forall i \in \{1, 2, \dots, s\} \\ & x_{ij} \in \{1, 2, \dots, s\} \end{aligned} \quad (7)$$

Tillman *et al.* [22] were among the first to solve the reliability–redundancy allocation problem (RRAP). Their method, known as *THK* (Tillman, Hwang & Kuo), is based on Hooke–Jeeves (H–J) pattern search [23]. Gopal *et al.* [24] developed a heuristic method called *GAG2* (Gopal, Aggarwal & Gupta-2) which adjusts the component reliability of one subsystem in each stage. Having the component reliability for each subsystem, the *GAG* (Gopal, Aggarwal & Gupta) approach [25] was applied to compute subsystem redundancy. Xu *et al.* [26] developed a heuristic which is known as *XXL* (Xu, Kuo & Liu). The algorithm finds the component redundancy by using a heuristic which is combined with an analytic approach to find the optimal reliability level.

Hsieh *et al.* [27] represented a GA approach for RRAP. Hikita *et al.* [28] applied a surrogate constraint method for RRAP in specific structures, including series–parallel and parallel–series systems.

Multistate System Reliability Optimization

More recently, reliability optimization algorithms have been applied for multistate systems (MSS) (*see Imprecise Reliability*). For these systems, component and/or system behavior exhibit varying performance, as opposed to traditional reliability where a component or system is either completely working or completely failed. Maximization of MSS requires efficient methods to estimate reliability. There are generally four methods for MSS reliability assessment: (a) the structure function approach (Brunelle and Kapur [29], Pourret *et al.* [30]), (b) the stochastic processes “Markov” approach (Xue and Yang [31]), (c) Monte Carlo simulation technique (*see Risk Measures and Economic Capital for (Re)insurers; Uncertainty Analysis and Dependence Modeling*) (Ramirez-Marquez and Coit [32]), and (d) the universal moment generating function approach (Levitin and Lisnianski [33], Ushakov [34, 35]).

Research for MSS reliability optimization considering one objective and several constraints have been presented recently. Ramirez-Marquez and Coit [36] proposed a heuristic to solve a multistate series–parallel system with binary capacitated components. In their study, the problem is formulated with the objective of minimizing the total cost associated with a system design constrained by a reliability performance index. Levitin *et al.* [37] used a GA for

solving the multistate RAP, where the system and its components have a range of performance levels. On the basis of the universal moment generating function (UMGF), they determined the system availability. Levitin [38] addressed the multistage expansion problem for multistate series–parallel systems. In this problem, the system-study period is divided into several stages. Later, Levitin [39] solved a redundancy optimization problem for multistate systems with fixed resource requirements and unreliable sources, subject to availability constraints.

Multiple-Objective System Reliability Optimization

Many system design initiatives are truly multiobjective. In addition to the maximization of system reliability, it is generally desirable to consider the minimization of other objectives such as cost, weight, etc. In such situations, the designer faces the problem of optimizing all objectives simultaneously.

As an example, consider a design problem where the objective is to determine the optimal design configuration that maximizes system reliability, minimizes the total cost and minimizes the system weight. The mathematical formulation of the problem is given below:

$$\left\{ \begin{array}{l} \max \left[R = \prod_{i=1}^s R_i(\mathbf{x}_i | k_i) \right], \\ \min \left[C = \sum_{i=1}^s \sum_{j=1}^{m_i} c_{ij} x_{ij} \right], \\ \min \left[W = \sum_{i=1}^s \sum_{j=1}^{m_i} w_{ij} x_{ij} \right] \end{array} \right\} \quad (8)$$

subject to

$$1 \leq \sum_{j=1}^{m_i} x_{ij} \leq n_{\max,i} \quad \forall i = 1, 2, \dots, s$$

$$x_{ij} \in \{0, 1, 2, \dots\}$$

where

c_{ij}, w_{ij} : cost and weight for the j th available component for subsystem i .

Multiple-objective versions of system reliability optimization problems have also been studied. Sakawa [40] considered a series system with

four objectives: maximization of system reliability, minimization of cost, weight, and volume. Sakawa proposed a method to derive Pareto-optimal solutions by optimizing the composite objective functions that were obtained as linear combinations of the four objective functions. The Lagrangian function for each composite problem was decomposed into parts and optimized by applying both the dual decomposition method and the surrogate worth trade-off method.

Dhingra [41] used a combination of goal programming and the goal attainment method to generate Pareto-optimal solutions in a four-stage series system to maximize system reliability and minimize cost, weight, and volume. Kulturel-Konak *et al.* [42] solved the problem using Tabu Search method with three objective functions: maximize reliability, minimize the cost of the system, and minimize the weight of the system. Coit *et al.* [43] proposed a multicriteria formulation to maximize the system reliability estimate and minimize the associated variance.

Multicriteria formulations using GAs can also be found. Busacca *et al.* [44] proposed a multiobjective GA approach that was applied to a safety system of a nuclear power plant. Huang *et al.* [45] proposed a new method of system reliability multiobjective optimization using GAs. They considered a reliability optimization model which contains two objective functions, simultaneously maximizing system reliability and minimizing system cost, subject to limits on weight and volume.

Recently, Taboada and Coit [46] and Taboada *et al.* [47] formulated the redundancy allocation problem as a multiobjective problem with the system reliability to be maximized, and cost and weight of the system to be minimized. The Pareto-optimal set was initially obtained using the fast elitist nondominated sorting genetic algorithm (NSGA-II) originally proposed by Deb *et al.* [48]. Then, the decision-making stage was performed by applying two proposed pruning methods to reduce the size of the Pareto-optimal set and obtain a smaller representation of the multiobjective design space.

Remote Sensing

Remote sensing can help inform risk assessment in several regards. It is especially advantageous when used in conjunction with geographic information systems (GISs), both of which support spatial specificity in scenarios of risk assessment (*see Spatial Risk Assessment*). Several realms of risk-relevant information can be addressed at least in part through these tandem technologies [1, 2].

One such aspect of risk-related information pertains to *exposure* to the agent(s) of concern. This type of information is indicative of the likelihood that a unit of interest will come under the influence of the agent(s) or stressor(s) being assessed. A second informational aspect pertains to the *sensitivity* or vulnerability of the unit(s) that may potentially be subject to the agent(s) of concern. This type of information is indicative of the degree of influence expected when a unit of interest is subjected to an agent of concern, as a function of level of exposure. A third informational aspect of interest concerns *condition* of units that are potentially involved in exposure to the impacting agent(s). This may be expressed variously in terms of value, health, functionality, diversity, impairment, etc. A fourth factor of analytical assessment addresses *resiliency* or propensity to recover from adverse influence after being subjected to an agent of concern. There are undoubtedly other aspects of assessment that can be aided by remote sensing, but these should be sufficient to induce investigative interest [3].

Sensors, Signals, and Synthesis

The traditional technology of remote sensing receives radiant signals *via* special sensors placed in perspective position at advantageous altitudes and then structures synoptic image information as digital data [4–6]. Systems can be configured to provide low spatial resolution over large areas, or high spatial resolution over smaller areas.

Standard signals are selected sections of the electromagnetic energy spectrum spanning visible and infrared wavelengths. Simultaneously sensed signals from several spectral sectors become *bands* of image information. It makes a substantial difference what spectral sections are selected. Figure 1

is a relatively low-resolution but expansive Landsat Thematic Mapper (TM) band spanning wavelengths of 0.63–0.69 μm in the red region of the spectrum for the risk-relevant context of forest fires and their after effects in China. This is a spectral section in which green plants absorb energy for photosynthesis, thus darkening the image in heavily vegetated areas. The large lighter patches in the lower-left quadrant represent areas where vegetation has been extensively impacted by large forest fires. This may be compared with Figure 2, which shows the thermal band (10.4–12.5 μm) of the same digital data that differentiates primarily between certain cold clouds, cool forests, and warmer exposed land surface areas.

Pseudosignals

Sometimes an individual spectral band is directly informative regarding conditions of interest, and sometimes it is not. Quite often an environmental condition of interest will express itself differently in particular bands, with the combination of expressions being fairly definitive [7, 8]. This is the case with green vegetation, which absorbs red radiation to support photosynthesis but strongly reflects infrared radiation in wavelengths just beyond the visible range. In this case, using some mathematical formulation for the difference between infrared and red that is normalized by the total of red and infrared will be indicative of the presence or absence of vegetation. Such formulations are conventionally called *vegetation indicators* or *vegetation indices*, often abbreviated as VIN. Figure 3 shows an image of one such formulation for the China fire digital image data.

It can be observed that the image of the vegetation indicator signal is somewhat darkened in the areas affected by the fires, indicating lesser cover of green vegetation. Likewise, the areas of clouds and the river show an absence of vegetation.

There is considerable scope for innovative formulation of such pseudosignals for incorporation into a multiband digital image dataset. Since the signal data are in digital form, there are no intrinsic constraints to such statistical synthesis. Owing to the typically large size of digital image datasets, however, special parsimonious data formats are used. Special software systems for image analysis are needed to access and analyze such data. Therefore, a partnership between remote sensing image analyst and risk assessment

Figure 1 Landsat TM red band image of areas in China affected by large forest fires

Figure 2 Landsat TM thermal image of areas in China affected by large forest fires

analyst is advantageous. It may also be noted that pseudosignals can also be synthesized from nonspectral sources such as digital elevation data to augment the analyses.

Compositional Classification

One of the standard statistical scenarios entails multivariate methods of categorical classification to produce maps of compositional components such as land cover classes. Land cover classification is routinely relevant to risk, since it is very likely to affect

Figure 3 Vegetation indicator pseudosignal for scene of China forest fire

exposure, sensitivity, condition, and resiliency. There are two major modes of mapping for such purposes, with multiple minor modifications on each [9].

One of the major modes of classificatory mapping is known in the image analysis jargon as *supervised classification*. This incorporates the intent of discriminant analysis by designating samples of each category as *training sets* to serve as prototypes for statistical pattern recognition processing. The supervision thus consists of designating the target classes in terms of training sets, with the mapping legend being predetermined.

The second major mode of classificatory mapping is called *unsupervised classification*, which is considerably more empirical since it does not require advance selection of class prototypes. This is initiated by conducting a statistical cluster analysis on the image data using one of a large variety of clustering strategies. A category name is then assigned to each of the resulting clusters on the basis of either existing information for some areas or data collected for the specific purpose of labeling clusters as the need arises. It is also common to refine the level of categorical detail using ancillary map information available in a GIS.

Modeling Spatial Interaction of Signals

As discussed with regard to pseudosignals, it is often the joint variation or interaction of different signal bands that is particularly informative with

respect to landscape patterns comprising the scene. The unsupervised approach to scene composition can be considerably extended to achieve modeling of the patterns of signal interaction at different levels of detail. This can be accomplished by compound statistical segmentation of a scene as described by Myers and Patil [10] to obtain *polypatterns*.

Polypatterns are derived by a four-stage segmentation sequence, which produces bi-level polypatterns that are contained in two bytes per image element (picture element = pixel). Since multiband digital image datasets normally use at least one byte per band, the polypatterns also accomplish image compression or informational condensation to occupy less computer memory resources. The aggregated A level of patterns is arranged as ordered overtones that can be rendered directly as a gray-tone image. The finer B level must be decompressed to be usable with generic image analysis software. The polypatterns serve as a model of the multiband image by enabling an approximated version of the original image dataset to be generated. The fidelity of the approximation can be checked and improved if desired. The A-level model contains 250 segments that can be analyzed in the manner of tabulated multivariate statistical data. The opportunities for statistical analysis are thus considerably expanded, since the original image data only support analysis on an element-by-element basis with elements typically numbering in the millions.

An image of the A-level model for the China fire context is shown in Figure 4. This model draws information from all bands and allows the major

Figure 4 Image overtones of A-level polypattern model for China forest fire context

variants of band interaction to be located. This image model captures the major patterns of joint variation for the image bands using only one byte of computer storage capacity per image element. In effect, this is a shaded map of segment locations with the shades being ordered in the same manner as the overall intensities of the segments. A particular advantage of such an A-level model is that it can be used in a GIS in the manner of a raster (cellular) map.

The nature of the four stages of development provides a bit more insight into the polypatterns. The first stage takes multiband image data and produces 250 pattern prototypes without specifying where the patterns occur in the scene. The second stage scans the image data relative to the pattern prototypes and produces a provisional pattern map. The third stage partially disaggregates the provisional patterns by successive splitting to obtain the base B-level model of patterns. The fourth stage (re)groups the B-level patterns into A-level aggregated patterns of the type shown in Figure 4.

Similar polypattern processing can be conducted on pseudosignals in the same manner as for spectral signals. This lends considerable flexibility to the analysis of spatial patterns for risk assessment.

Components of Change

The patterns and progress of landscape changes are very important in relation to risk assessment, and this is another area in which remote sensing is relevant. It is fairly intuitive that repeating images over time with the same sensor and examining differences in the respective bands should be revealing with respect to patterns of change. A straightforward extension from single-band difference to multiband difference is obtained by Euclidean distance, which is the square root of the sum of squared differences for the respective bands. This is equal to the distance moved by an image element in spectral space between imaging occasions, and is therefore usually called *change vector* analysis. Spectral space (or spectral feature space) consists of band values as axes on a graph having as many dimensions as there are bands. This reduces to the single-band difference if there is only one band, and is similar to the quadratic mean change in lending emphasis to the bands having the larger changes. There are likewise several other ways in which indicators of spectral change could be

formulated, as for example, using Manhattan distance instead of Euclidean distance. Manhattan distance is effectively the sum of the band differences, and therefore does not give disproportionate emphasis to large changes in band values *versus* smaller changes.

It is also possible to make what might be called a *multi-indicator change image* by including several different indicators as if they were bands in a multiband digital image. For example, this might include differences for the respective bands along with a change vector. Multi-indicator change images tend to be complicated to interpret by conventional image analysis, but lend themselves nicely to modeling spatial interaction of signals as outlined above. The change interaction model is again much more parsimonious than its parent change image dataset, and can be interpreted at the segment level. This idea of image modeling for multiband composites can likewise be extended to multitemporal investigations involving more than two imaging occasions. Change indicators can be compiled for each successive pair of occasions, and then composited in the manner of multiband digital data for modeling. Patterns in interaction obtained in modeling thus reveal patterns of temporal change.

The polypattern approach to image modeling confers still further advantage for change analysis in a rather different manner. Spatial, as opposed to spectral, matching of A-level patterns can be done between imaging occasions. Each pattern in one date thus has a counterpart pattern in the other date. Inconsistencies in occurrences of counterparts between dates are indicative of change. This approach does not presume that the bands recorded by the sensors on the two occasions are exactly the same.

Color Coding

It is worthy to note the important role of tricolor coding images in remote sensing. Human vision obtains sense of color as mixtures of red, green, and blue light. This allows color renditions to be obtained

from three image bands by coloring one in shades of red, one in shades of green, and one in shades of blue (RGB). Tricolor composites are essential to take full advantage of remote sensing imagery for visual interpretation. Unfortunately, color images are also expensive to publish and have been considered an unaffordable luxury for this writing.

Repair, Inspection, and Replacement Models

Maintenance of stochastically deteriorating systems (see **Reliability Growth Testing**) has received much attention, as systems used in production of goods and delivery of services constitute the vast majority of most industries' capital. An optimal maintenance policy (see **Role of Risk Communication in a Comprehensive Risk Management Approach**) is important to prevent the occurrence of system failure, improve system reliability, and reduce maintenance costs. A maintenance policy is a function whose range is the set of possible maintenance actions, the action space, and whose domain is the set of possible realizations in the system's history, the information space. Repair, inspection, and replacement are the main elements of the action space. An optimal maintenance policy results from optimization of a mathematical maintenance model in which both costs and benefits of maintenance are quantified. Results from early developments of maintenance models are summarized by McCall [1] and Barlow and Proschan [2].

Although the industry recognized the importance of maintenance, it took some time before it adopted a scientific approach toward maintenance. The reasons might be that the effects of poor maintenance only become manifest in the medium to long term, and that the direct benefit of effective maintenance is difficult to measure: "the true value of maintenance is given in terms of events that do not occur, which makes the assessment of the value of these measures at best speculative" [3].

Over the years, the complexity of maintenance models (see **Role of Risk Communication in a Comprehensive Risk Management Approach; Structural Reliability; Maintenance Modeling and Management**) has increased in response to the more complex maintenance problems in real life. Many of the important early maintenance models, such as age and block-replacement models possessed an elegance and simplicity that led to easily implementable policies. These models were later generalized to describe real situations more accurately. Some of the new results are complex and require powerful computers for implementation. However, to appreciate these complex models, understanding of the

basic models is required. Before introducing some basic maintenance models for single-unit and multiunit systems in the sections "Single-Unit Maintenance Models" and "Multiunit Maintenance Models", we discuss the general characteristics of maintenance models in the section "Model Characteristics". For more information about generalizations of these basic models, we refer to excellent overview papers in the literature [1, 4–10].

Model Characteristics

We discuss some important general characteristics of maintenance models.

States of the System

Consider a system consisting of $n(\geq 1)$ units and denote by $X_i(t)$, $i = 1, \dots, n$, $t \geq 0$, the state of the i th unit at time t . Then the state of the system at time t is given by the random vector $\mathbf{X}(t) = (X_1(t), X_2(t), \dots, X_n(t))$. The state space Ω_i of the i th unit is the set of all its possible states, and the state space of the system is $\Omega = \prod_{i=1}^n \Omega_i$. Maintenance policies are conditioned on the state of the system as they describe the action that should be taken for each $\omega \in \Omega$. Several quantities can describe the state of a unit, e.g., deterioration level, age, or number of spare units, and similar quantities can describe the system.

Available Actions

In general, three main actions are considered in maintenance models: repair, replace, or do nothing. Which action should be taken depends on several factors, such as the state of the system at the time of action, the objective function, and the time horizon. If the state of the system is not known, then inspection of the system is also a possible action. McCall [1] termed maintenance models where the state of the system subject to stochastic failure is always known with certainty *preventive* maintenance models, and models where the state of the system subject to stochastic failure is unknown unless either inspection or replacement is carried out *preparedness* maintenance models.

Several different levels of repair, replacement, and inspection characterize different maintenance models. For example, if repair or replacement of a failed

unit restores function to the system, but the system's failure rate remains as it was just before failure, then the action is called *minimal* repair. If there is economies of scale in the repair or replacement activity, and the repair or replacement of a failing unit provides an opportunity for preventive maintenance of other units, it is called *opportunistic* repair or replacement. The system can be *continuously* monitored, in which case the state of the system is known at every moment, or inspection can only take place at certain *discrete* times. These actions are explained in greater detail in the sections titled "Single-Unit Maintenance Models" and "Multiunit Maintenance Models".

Time Horizon

It is important to make a distinction between maintenance models with finite and infinite time horizons, the latter have received more attention in the literature as the corresponding optimization problems tend to be easier. Optimal policies are obtained by optimization of an objective function, possibly subject to a set of constraints. In case of an infinite time horizon, the optimal policy is *stationary* (i.e., constant over time). For a finite time horizon, the optimal policy is recalculated at each replacement or repair time by optimizing the objective function over the remaining time. Such *sequential* policies appear to be most important in industries where equipment is subject to rapid technological change. The end point of a finite horizon can be fixed or random, the latter, e.g., if it depends on a finite number of spare parts [11].

Knowledge of the System

On the basis of the knowledge of the system, one can make a distinction between maintenance models with complete and partial/incomplete information, e.g., on the system's failure time distribution, its current state, or its cost structure [8]. If the current state of the system is unknown, inspection is required, which can be perfect or imperfect. McCall [1] suggests four different ways of dealing with incomplete information: (a) minimax maintenance policies if one has virtually no information, (b) maintenance policies based on bounding techniques if one possesses some information regarding the stochastic behavior of the system, e.g., the expected value of the failure time or that its failure rate is increasing, (c) Bayes

adaptive models (*see Bayesian Statistics in Quantitative Risk Assessment*) if one has some relevant subjective information and statistical information will accrue over time, and (d) estimated parametric maintenance models if one has detailed knowledge of the failure distribution and enough data to estimate the parameters. Maintenance models with incomplete information have not received much attention in the literature. Recently, adaptive nonparametric predictive maintenance models have been presented, where uncertainty about the failure time of a future unit is quantified on the basis of its exchangeability with n observed failure times, and where optimal policies adapt to available process information [12, 13].

Model Types

Maintenance models can be classified according to *discrete* or *continuous* time being used. In the first case, system monitoring and actions only take place at discrete time points. Another possible distinction considers the deterioration process of the system, leading to *deterministic* and *stochastic* maintenance models. We restrict attention to stochastically deteriorating systems. Maintenance models can also be classified with regard to the type of system considered, e.g., *single-unit* or *multiunit* systems, and whether or not multiple units are dependent. Interactions between units can be classified into three different types [6]:

1. **Economic dependency**
The cost structure of replacement and maintenance has dependencies between the units. Either costs can be saved when several units are jointly maintained (economies of scale), or the opposite happens if simultaneous downtime of the units is undesirable and hence maintenance must be spread out as much as possible.
2. **Structural dependency**
Some working units have to be replaced or dismantled to replace or repair failed units.
3. **Probabilistic dependency**
The state of one unit influences the failure time distribution of other units, or common-cause failures occur that bring about simultaneous failures and hence correlate the lifetimes.

If all units in a system are economically, structurally, and stochastically independent, maintenance policies for single-unit systems can be applied to

the multiunit system. But if any units in a system are dependent upon each other, an optimal repair or replacement decision for one unit is not necessarily optimal for the whole system, so interactions cannot be neglected in maintenance policies. The section “Single-Unit Maintenance Models” presents maintenance models for single-unit systems, and the section “Multiunit Maintenance Models”, for multiunit systems.

Optimality Criteria

Optimal maintenance policies (*see Economic Criteria for Setting Environmental Standards*) obviously depend on the chosen objective function. When considering an infinite time horizon, common criteria are minimization of long-run expected (discounted) costs or long-run expected downtime, or maximization of long-run expected availability, all per unit time. If the process considered does not change over the infinite horizon and the replacement units all have the same failure time distribution, then the renewal reward theorem can be applied. This implies, e.g., that the long-run expected costs per unit time are equal to the expected costs per cycle divided by the expected cycle length, where a cycle is the time between consecutive renewals. In practice, even though such a long period for the same process is not realistic, the renewal reward optimality criterion is often considered attractive and reasonable, partly because of its mathematical simplicity.

During the last decade [14–16], there has been increasing interest in adaptive replacement strategies (*see Imprecise Reliability*), where instead of assuming complete knowledge of a system’s failure time distribution, one uses information from the process to update the distribution used for deriving the optimal replacement strategy for the next system. Such an adaptive approach undermines the use of the renewal reward criterion, as one explicitly does not use the same replacement strategy over a very long period of time. In [14, 17] the use of a “one-cycle” optimality criterion is proposed, aiming at minimal expected costs per unit time for the single cycle corresponding to the system considered. Comparisons of the renewal reward and one-cycle criteria are given in [18, 19].

When considering a finite time horizon, optimal sequential maintenance policies can be obtained, e.g., by minimizing the expected total (discounted) costs or downtime of the system over the whole time

horizon. Unfortunately, analytic identification and practical implementation of such a sequential policy tends to be prohibitively complex. Hence, asymptotic approximations (e.g., by using the renewal reward criterion) are more frequently employed.

Methods of Solutions

The primary optimization techniques used to derive optimal policies include (non) linear programming, dynamic programming (*see Role of Alternative Assets in Portfolio Construction; Reliability Optimization; Optimal Stopping and Dynamic Programming*), Markov decision methods, decision analysis techniques, search techniques, and heuristic approaches. Policies that require detailed descriptions of each possible realization of the system or that have complicated forms are often analytically difficult and costly to implement. Therefore, attention is normally confined to classes of policies that possess a simple form, which often determines the appropriate optimization techniques.

Single-Unit Maintenance Models

We consider maintenance models (*see Reliability Integrated Engineering Using Physics of Failure; Quantitative Reliability Assessment of Electricity Supply*) for systems consisting of only a single unit: repair models, inspection models, shock models, and data-based models. We present the foundations of the models and mention some generalizations; see [1, 4, 7, 8, 10] for overviews, including more generalizations. We should emphasize that not all maintenance models can be classified into one of these categories.

Repair Models

The basic period preventive maintenance model was introduced by Derman [20] and extended by Klein [21] (see also [2]). Consider a unit that is observed at discrete time points, and let $X(n)$ be the deterioration level of the unit at time n . The state space of the unit is the set $\Omega = \{0, 1, \dots, L\}$, where state 0 denotes a new or completely renovated unit and state L , an inoperative or failed unit. It is assumed that (a) the unit deteriorates stochastically according to a time-homogeneous Markov chain with

one-step transition probabilities $p_{ij} = P\{X(n+1) = j | X(n) = i\}$, $i, j \in \Omega$, $n = 0, 1, \dots$; (b) without replacement or repair, the unit does not return to state 0, so $p_{i0} = 0$ for $i \in \Omega \setminus \{L\}$; (c) the unit must be replaced upon failure, i.e., $p_{L0} = 1$; (d) the unit will eventually fail, the underlying Markov chain $\{X(n), n = 0, 1, \dots\}$ has a single ergodic class, and the steady-state distribution exists, i.e., there is an n such that $p_{iL}(n) > 0$ for each $i \in \Omega \setminus \{L\}$, where $p_{ij}(n) = P\{X(n+m) = j | X(m) = i\}$ are the n -step transition probabilities.

The unit can be replaced preventively, at cost c_p , to avoid failure or further deterioration, whereas replacement upon failure costs $c_f > c_p$. Let $N_p(t)$ and $N_f(t)$ be the number of preventive and corrective replacements during $[0, t)$, respectively. The objective is to minimize the long-run expected costs per unit time,

$$\lim_{t \rightarrow \infty} \frac{c_p E[N_p(t)] + c_f E[N_f(t)]}{t} \quad (1)$$

Replacement decisions are summarized by a set of decision rules based on the entire history of the process. Derman [22] established conditions that enable restriction to stationary nonrandomized rules, showing that if $\sum_{j=k}^L p_{ij}$ is nondecreasing in $i \in \Omega \setminus \{L\}$, for each $k \in \Omega$, then a *control-limit* rule is optimal, i.e., there is a state $i^* \in \Omega$ such that the unit should be replaced if and only if the observed state is $k \geq i^*$. The additional condition implies that the Markov chain is increasing in failure rate (IFR), i.e., without replacements the probability of deterioration increases as the initial state increases.

This basic model has received much attention in the literature and many generalizations, with respect to, for example, the state space and cost structure, have been presented. See the review papers mentioned earlier for overviews of generalizations.

One of the best known repair models with maintenance not restricted to a set of discrete time points is the *age-replacement model* (see **Imprecise Reliability; Reliability Data**) [2], where a unit is replaced upon failure or upon reaching the age T , whichever occurs first. Let F be the *known* cumulative distribution function (cdf) of the unit's failure time, f its probability density function (pdf), then the hazard rate of the unit at age x is $h(x) = f(x)/(1 - F(x))$, where $h(x) dx$ can be interpreted as the probability that a unit of age x will fail in the small interval $(x, x + dx]$.

When considering an infinite time horizon, Barlow and Proschan [2] proved that the optimal age-replacement policy is nonrandom if the underlying failure time distribution is continuous. Application of the renewal reward theorem implies that the long-run expected costs per time unit for replacement strategy $T > 0$ are equal to the expected costs per cycle divided by the expected cycle length, where a cycle is the time between two consecutive replacements, so equation (1) can be written as

$$C(T) = \frac{c_p(1 - F(T)) + c_f F(T)}{\int_0^T (1 - F(x)) dx} \quad (2)$$

Let the optimal strategy be denoted by T^* (which might be infinite), then the first-order necessary condition for optimality of a finite T^* [2] is

$$h(T) \int_0^T (1 - F(x)) dx - F(T) = \frac{c_p}{c_f - c_p} \quad (3)$$

For monotonically strictly increasing $h(T)$, Barlow and Proschan [2] proved that if $h(\infty) > c_f/((c_f - c_p)E[X])$, with $E[X]$ the first moment of F , then equation (3) has a unique finite solution T^* , else it has no finite solution, and the unit should only be replaced on failure.

Example 1 (Age-replacement model) Suppose that the failure time of a unit has a Weibull distribution with shape parameter 2 and scale parameter 1 (notation: $W(2,1)$), so $f(t) = 2t e^{-t^2}$, $t \geq 0$ and $h(t) = 2t$, and let $c_p = 1$ and $c_f = 10$. We would like to find the optimal age-replacement strategy T^* that minimizes the long-run expected costs per unit time as given in equation (2). As the hazard rate $h(t)$ is monotonically strictly increasing in t and $h(\infty) > c_f/((c_f - c_p)E[X])$, it follows that equation (3) has a unique finite solution $T^* = 0.3365$, with $C(T^*) = 6.0561$. If no preventive replacement were carried out, the long-run expected costs per unit time would be $C(\infty) = 11.2838$.

When considering a finite time horizon, the problem becomes much more difficult. If F is continuous, then for any finite time horizon, there exists a minimum cost age-replacement policy [2], but no general analytic formula is available for its calculation. In [2] it is shown how to calculate the optimal policy for a particular case.

Many variations and generalizations of the age-replacement model have been presented, some involving refined cost functions. Nakagawa and Osaki [23] considered age replacement for a two-unit redundant system, where one of the identical units is in operation and the other is in standby and immune to failure or aging effects. Dekker and Dijkstra [24] considered opportunity-based age replacement, with preventive replacement at the first opportunity after reaching a predetermined threshold age.

The class of *minimal repair models* (see **Repairable Systems Reliability**) is also important. There are many instances in which complex systems with several components are regarded as single units for maintenance purposes. However, the performance of complex systems depends on the individual components. At system failure, a decision is required on whether to replace the system or to repair (replace) the failed component and reset the system to operation. If a repair or replacement of the failed component restores function to the entire system but the system's failure rate remains as it was just before failure, then it is called *minimal repair*. Since the failure rate of most complex systems increases with age, it would become increasingly expensive to maintain operation by minimal repair. The question is then, when is it optimal to replace the entire system instead of performing minimal repair?

Barlow and Hunter [25] first discussed this problem, using a periodic replacement model with minimal repairs between replacements. It is assumed that there is only minimal repair after failures, so without any effect on the system's increasing failure rate $h(t)$. Replacement occurs at times $T, 2T, 3T, \dots$, and the cost of a minimal repair c_m is less than the cost of replacing the entire system c_s . The problem is to minimize $C(T)$, the long-run expected costs per unit time under policy $T > 0$, which, using the renewal reward theorem is given by

$$C(T) = \lim_{t \rightarrow \infty} \frac{c_m E[N_m(t)] + c_s E[N_s(t)]}{t} = \frac{c_m \int_0^T h(x) dx + c_s}{T} \quad (4)$$

where $N_m(t)$ and $N_s(t)$ are the number of minimal repairs and system replacements during $[0, t)$, respectively. Let the optimal strategy be denoted by T^* ,

then the first-order necessary condition for optimality [2] is

$$\int_0^T [h(T) - h(x)] dx = \frac{c_s}{c_m} \quad (5)$$

If there is an interval $[0, b)$, with $0 < b \leq \infty$, on which $h(t)$ is continuous and unbounded, then equation (5) has a solution, which is unique if $h(t)$ is strictly increasing and differentiable [2]. Generalizations of this model include, for example, minimal repair costs that depend on the number of such repairs since the last replacement or on the age of the system [26, 27]. In [28], both the replacement and repair costs may vary.

For a finite time horizon, the class of *sequential replacement policies* (see **Product Risk Management: Testing and Warranties**) is important. Under a sequential policy, the next planned replacement is selected to minimize expected expenditure during the remaining time. For an analysis of a sequential replacement model, see [2].

Inspection Models

Inspection models consider situations in which faults are discovered only by inspection, often after some time has elapsed since a failure occurred. The goal is to determine inspection policies that minimize the total expected costs resulting from both inspection and failure. At each decision moment, one must decide which maintenance action to take and when next to inspect the system.

In the basic model [29], it is assumed that upon detection of failure the problem ends, that is, no replacement or repair takes place. Each inspection incurs a cost, and there is a penalty cost associated with the lapsed time between occurrence and detection of a failure. We assume that (a) system failure is known only through inspection, (b) inspection takes negligible time and does not affect the system, (c) the system cannot fail while being inspected, (d) each inspection entails a fixed cost c_i , (e) undiscovered system failure costs c_s per unit of time, and (f) inspection ceases upon discovery of a failure. Let $N_i(t)$ be the number of inspections during $[0, t]$, γ_t the interval between failure and its discovery if failure occurs at time t , and F the cdf of the failure time. Then the expected costs are

$$C = \int_0^\infty (c_i(E[N_i(t)] + 1) + c_s \gamma_t) dF(t) \quad (6)$$

An optimum inspection policy specifies successive inspection times $x_1 < x_2 < \dots$ for which C is minimized. It has been proved that the optimal policies are nonrandom [29]. If we define $x_0 = 0$ and require that the sequence $\{x_n\}$ be such that the support of F is contained in $[0, \lim_{n \rightarrow \infty} x_n)$, to exclude the possibility of undetected failure occurring with positive probability, then equation (6) becomes

$$C = \sum_{k=0}^{\infty} \int_{x_k}^{x_{k+1}} (c_i(k+1) + c_s(x_{k+1} - t)) dF(t) \quad (7)$$

Barlow *et al.* [29] presented several important results. An optimal inspection schedule exists if F is continuous with finite first moment. If it is known that failure must occur by time $T > 0$, so $F(T) = 1$, then if $F(t) \leq (1 + (c_s/c_i)(T - t))^{-1}$ for $0 \leq t \leq T$ the optimal inspection schedule consists of a single inspection performed at time T . Otherwise, in addition to the inspection at time T , one or more earlier inspections are required. They also presented an algorithm for computing the optimum inspection policy under certain conditions. Beichelt [30] generalized this basic model by allowing repair upon detection of failure. He used a minimax approach to find the optimal inspection policy in case of partially known failure time distributions. Luss [31] considered the basic repair model of Derman [20] in which both corrective and preventive replacement are allowed, but with the state of deterioration only known through inspection. He developed a simple iterative algorithm for the optimal control-limit policy and corresponding optimal inspection intervals in all states, minimizing the long-run expected costs per unit time. Many further generalizations have been presented, including imperfect or unreliable inspections.

Christer and Waller [32] presented models for optimal inspection and replacement using *delay time analysis* (see **Accelerated Life Testing; Availability and Maintainability**). The delay time h of a fault is the time lapse from when a fault could first be noticed until the time when its repair can be delayed no longer because of unacceptable consequences. A repair may be undertaken any time within this period. They assume that (a) an inspection takes place every T time units, costs I , and requires d time units, (b) inspections are perfect, (c) defects identified at an inspection will be repaired within the inspection period, (d) the initial instant at which a defect may be assumed to first arise is uniformly distributed over

time since the last inspection, independent of h , and faults arise at the rate of k per unit time, (e) the pdf f of the delay time is known, or can be estimated. The basic model is as follows: Suppose that a fault arising within the period $[0, T)$ has a delay time in the interval $[h, h + dh)$. This fault will be repaired as a breakdown repair if the fault arises in period $(0, T - h)$, otherwise as an inspection repair. The probability of a fault arising as a breakdown, for an inspection policy of period T , is

$$b(T) = \int_0^T \left(\frac{T - h}{T} \right) f(h) dh \quad (8)$$

If the average downtime for breakdown repair is d_b and the average breakdown and inspection repair costs are c_b and c_i , respectively, then the expected downtime per unit time for inspection policy T is

$$D(T) = \frac{1}{T + d} \{kT d_b b(T) + d\} \quad (9)$$

with total expected costs per unit time equal to

$$C(T) = \frac{1}{T + d} \{kT [c_b b(T) + c_i (1 - b(T))] + I\} \quad (10)$$

The optimal inspection policy can be calculated easily, as the cost model is simple.

Example 2 (Delay time model) Consider an inspection model for a unit with delay time pdf $f(h) = 0.05 e^{-0.05h}$ for $h \geq 0$. Assume that faults arise at a rate of 0.1 faults per hour, and that the downtime for breakdown repair (d_b) and for inspection and subsequent repairs (d) are 0.5 and 0.35 hours, respectively. The average costs of a breakdown repair $c_b = 10$ and of inspection repair $c_i = 5$. The cost of inspection $I = 2$. The probability of a fault arising as a breakdown and the expected downtime per unit time, for inspection policy T , are

$$b(T) = 1 - \frac{20}{T} (1 - e^{-0.05T}) \quad \text{and} \quad D(T) = \frac{1}{T + 0.35} (0.05T + e^{-0.05T} - 0.65) \quad (11)$$

and the total expected costs per hour are

$$C(T) = \frac{1}{T + 0.35} (T - 8 + 10 e^{-0.05T}) \quad (12)$$

Minimizing the total expected costs per hour yields $T^* = 14.99$, so inspection should take place every 15 hours with minimal total expected costs per hour of 0.764. The corresponding probability of a fault arising as a breakdown is 0.296, while the corresponding expected downtime per hour equals 0.03729 hours.

If the objective is to minimize the expected downtime per hour, we obtain optimal $\tilde{T} = 24.02$, so inspection should take place every 24 hours, and $D(\tilde{T}) = 0.03496$. In this case, the total expected costs per hour are 0.781 and the probability of a breakdown repair during an inspection period equals 0.418. Note that although the expected downtime per hour under policy $\tilde{T}$ is smaller than under policy T^* , the probability of a breakdown repair has increased owing to the longer inspection period.

Several generalizations of this basic delay time model have been presented, including delay time models with imperfect inspection. An important result with respect to the assumption of known delay time distribution is obtained by Coolen and Dekker [33]. They considered a model in which a system is subject to several failure modes (competing risks), but there exists an intermediate state to failure that can be detected by inspection only for one failure mode. This intermediate state corresponds to the delay time for that failure mode. They showed that, in practice, the first two moments of the delay time distribution are sufficient to obtain the optimal inspection policy so that assumption (e) can be relaxed, and also that competing risks do not need to be considered in determining the optimal inspection policy.

Shock Models

We consider systems that are subject to shocks, where each shock causes an amount of damage that accumulates additively until replacement or failure. The time between shocks and the damage caused by a shock are random variables that may depend on $X(t)$, the accumulated damage at time t . The system is replaced upon failure at a cost $c(\Delta)$, where Δ denotes the state of failure, but it may also be replaced before failure at a cost $c(x) \leq c(\Delta)$ if the damage level at the time of replacement is x . It is assumed that the replacement cost function $c(\cdot)$ is a nondecreasing function of the accumulated damage, that replacements take a negligible amount of time,

and that damaged systems are replaced by new, identical systems. Let ξ be the failure time and T the replacement time. Then, using the renewal reward theorem, the long-run expected costs per unit time are

$$C(T) = \frac{P\{T < \xi\}E[c(X(T))] + P\{T = \xi\}c(\Delta)}{E[T \cap \xi]} \quad (13)$$

Most shock models give conditions under which the optimal policy takes the form of a control-limit policy, i.e., the system is replaced when the accumulated damage exceeds a critical level α or at failure, whichever occurs first. In this case, the replacement time T is

$$T = \min\{\inf\{t > 0 : X(t) > \alpha\}, \xi\} \quad (14)$$

Many generalizations of this model have been presented, including shock models where the cumulated damage is a nondecreasing semi-Markov process and failures can occur at any time [34], and models where system deterioration occurs both continuously and due to shocks [35] (*see Mathematics of Risk and Reliability: A Select History*).

Data-Based Models

We present two maintenance models for which the failure time distribution is unknown, but for which past realizations of the failure time are available. According to McCall [1], one way to circumvent the difficulty of incomplete information is by means of *Bayes adaptive models*. There are a few earlier papers known in literature concerning Bayesian analysis of maintenance models, but Mazzuchi and Soyer [14] were the first to provide a fully Bayesian analysis of the age and block-replacement models with minimal repair (see section titled “Group Maintenance Models”). In their approach to age replacement, let t_A be the replacement age, T the time to failure, and c_f and c_p the corrective and preventive replacement costs. They model the time to failure with a Weibull distribution with unknown scale and shape parameters α and β . The length of the time between successive replacements, and the costs per unit time, are random variables defined by

$$\begin{aligned} L(T, t_A) &= \begin{cases} t_A & \text{if } T \geq t_A \\ T & \text{if } T < t_A \end{cases} \quad \text{and} \\ C(T, t_A) &= \begin{cases} \frac{c_p}{t_A} & \text{if } T \geq t_A \\ \frac{c_f}{T} & \text{if } T < t_A \end{cases} \end{aligned} \quad (15)$$

The uncertainty about α and β is expressed by prior distributions, based on expert judgments and obtained by elicitation. These can be updated when failure and replacement data become available. The optimal policy is obtained as the value t_A that minimizes $E_{\alpha,\beta}[E[C(T, t_A)|\alpha, \beta]]$. Note that they do not use the renewal reward theorem, as its use is not appropriate in case of an adaptive policy.

If the failure distribution is unknown, but failure data are available, one can consider maintenance policies within an *adaptive nonparametric predictive inference (NPI) framework* (see **Imprecise Reliability**), as presented in [12, 13, 17] for adaptive (opportunity-based) age replacement. NPI is based on Hill's assumption A_n [36, 37]. Denoting n ordered, observed failure times by $x_1 < x_2 < \dots < x_n$, A_n specifies direct probabilities for a future failure time X_{n+1} by

$$P\{X_{n+1} \in (x_j, x_{j+1})\} = \frac{1}{n+1}, \quad j = 0, \dots, n \quad (16)$$

where $x_0 = 0$ and $x_{n+1} = \infty$, or $x_{n+1} = r$ if we can safely assume a finite upper bound r for the support of X_{n+1} . This approach is suitable if there is hardly any knowledge about the random quantities of interest, other than the n observations. It does not provide precise probabilities for all possible events of interest, but it does provide optimal bounds for all probabilities by application of De Finetti's Fundamental Theorem of Probability (see **Subjective Probability**) [38]. Such bounds are lower and upper probabilities within the theory of interval probability [37]. We illustrate this approach with the age-replacement problem based on the renewal reward criterion as described in the section titled "Repair Models" [12]; opportunity-based age replacement and age replacement with a one-cycle criterion are presented in [13] and [17].

Denote by $S(x) = 1 - F(x)$ the survival function. Instead of assuming a known probability distribution F for the time to failure of a unit, imprecise predictive survival functions for the time to failure of the next unit are used based on A_n . The maximum lower bound $\underline{S}(x)$ ("lower survival function") and the minimum upper bound $\bar{S}(x)$ ("upper survival function") are obtained by shifting the probability mass in the interval in which x lies to

the left and right end point of the interval respectively,

$$\underline{S}_{X_{n+1}}(x) = S_{X_{n+1}}(x_{j+1}) = \frac{n-j}{n+1} \quad \text{for } x \in (x_j, x_{j+1}], \quad j = 0, \dots, n \quad (17)$$

and

$$\bar{S}_{X_{n+1}}(x) = S_{X_{n+1}}(x_j) = \frac{n+1-j}{n+1} \quad \text{for } x \in [x_j, x_{j+1}), \quad j = 0, \dots, n \quad (18)$$

The cost function $C(T)$ (equation (2)) is decreasing as function of $S(\cdot)$, in the sense that $C(T)$ decreases if $S(x)$ increases for $x \in (0, T]$. This implies that these lower and upper survival functions for X_{n+1} straightforwardly lead to the following lower bounds $\underline{C}$ and upper bounds $\bar{C}$ for the cost functions,

$$\begin{aligned} \underline{C}_{X_{n+1}}(x_j) &= \frac{jc_f + (n+1-j)c_p}{(n+1-j)x_j + \sum_{l=1}^j x_l}, \\ &\quad j = 1, \dots, n+1 \\ \underline{C}_{X_{n+1}}(T) &= \frac{jc_f + (n+1-j)c_p}{(n+1-j)T + \sum_{l=1}^j x_l}, \\ &\quad T \in (x_j, x_{j+1}), \quad j = 0, \dots, n \\ \bar{C}_{X_{n+1}}(x_j) &= \frac{jc_f + (n+1-j)c_p}{(n+1-j)x_j + \sum_{l=1}^{j-1} x_l}, \\ &\quad j = 1, \dots, n+1 \\ \bar{C}_{X_{n+1}}(T) &= \frac{(j+1)c_f + (n-j)c_p}{(n-j)T + \sum_{l=1}^j x_l}, \\ &\quad T \in (x_j, x_{j+1}), \quad j = 0, \dots, n \end{aligned} \quad (19)$$

Coolen-Schrijner and Coolen [12] showed that the global minimum of $\bar{C}_{X_{n+1}}(\cdot)$ is assumed in one of the points x_j , $j = 1, \dots, n$, and the minimum of $\underline{C}_{X_{n+1}}(\cdot)$ on $(0, x_n]$ is assumed in one of the x_j^- , $j = 1, \dots, n$, with x_j^- , meaning "just before x_j ".

Table 1 NPI adaptive age replacement

	$T_{\text{low},n+1}^*$	$\Delta_{\text{low},n+1}$	$T_{\text{low},n+2}^*$	$\Delta_{\text{low},n+2}$	$T_{\text{up},n+1}^*$	$\Delta_{\text{up},n+1}$	$T_{\text{up},n+2}^*$	$\Delta_{\text{up},n+2}$
Mean	0.3553	0.0313	0.3529	0.0310	0.3694	0.0315	0.3673	0.0312
Median	0.3453	0.0152	0.3433	0.0151	0.3588	0.0157	0.3564	0.0155
SD	0.0926	0.0414	0.0917	0.0409	0.0948	0.0412	0.0941	0.0409

If we assume a known upper bound r for the support of X_{n+1} , $\underline{C}_{X_{n+1}}(\cdot)$ is also strictly decreasing on (x_r, r) , so we must also consider $\underline{C}_{X_{n+1}}(r^-)$ for finding the global minimum on $(0, r]$. If this minimum is attained in r^- , then it is better not to replace preventively.

Minimization of the lower and upper cost functions with regard to age replacement of unit $n+1$ may lead to two different optimal replacement times, $T_{\text{low},n+1}^*$ and $T_{\text{up},n+1}^*$. We now present a general theory for which it is not relevant to make the distinction, in which case we use T_{n+1}^* as generic notation for an optimal age-replacement time that was used for unit $n+1$. Under the optimal age-replacement strategy for X_{n+1} , the observation for X_{n+1} is either a failure time less than T_{n+1}^* , in which case the unit was replaced correctively, or a right-censored observation at T_{n+1}^* , in which case the unit was replaced preventively. To study the adaptive nature of this procedure, we now want to consider the optimal age-replacement strategy for unit $n+2$. If unit $n+1$ fails before T_{n+1}^* , we can directly apply the results presented before on the $n+1$ failure times, with A_n replaced by A_{n+1} to obtain the optimal age-replacement time for unit $n+2$. If unit $n+1$ is preventively replaced at $T_{n+1}^* = x_k$ for some $k \in \{1, \dots, n\}$, the relevant data set now consists of the n original failure times together with a right-censored observation at x_k . For NPI based on such data, the assumption rc- A_{n+1} [39] can be applied, leading to upper and lower survival functions for X_{n+2} , which consequently lead to lower and upper cost functions for X_{n+2} . This updating process is presented in [12], and illustrated by the following example.

Example 3 (NPI age-replacement model) A simulation study of 10 000 runs was carried out, in which in each run 100 failure times were simulated from a W(2,1) distribution, enabling us to compare the optimal replacement times corresponding to the NPI lower and upper cost functions with the theoretical optimal replacement time $T^* = 0.3365$ from Example 1, assuming the same costs as in that example. For each run, we calculated the optimal age-replacement

times for units $n+1$ and $n+2$, the latter after a further observation for unit $n+1$ had been simulated and its optimal replacement strategy applied, by minimizing the lower and upper cost functions for X_{n+1} and X_{n+2} . Table 1 gives some results with the following notation: $T_{\text{low},n+i}^* = \arg\min \underline{C}_{X_{n+i}}(T)$, $T_{\text{up},n+i}^* = \arg\min \overline{C}_{X_{n+i}}(T)$, $\Delta_{\text{low},n+i} = (C(T_{\text{low},n+i}^*) - C(T^*)) / C(T^*)$, $\Delta_{\text{up},n+i} = (C(T_{\text{up},n+i}^*) - C(T^*)) / C(T^*)$, $i = 1, 2$, where $C(\cdot)$ is the cost function defined in equation (2). These Δ 's indicate how good the NPI optimum replacement times are compared to the theoretical optimum, judged by comparing the loss in long-run expected costs per unit time if the NPI optimum is used instead of the theoretical optimum, as fraction of the long-run expected costs per unit time in the theoretical optimum.

The means of the $T_{\text{low},n+i}^*$ and $T_{\text{up},n+i}^*$, $i = 1, 2$, from the simulations are all larger than the theoretical T^* . However, as the distributions of the values of $T_{\text{low},n+i}^*$ and $T_{\text{up},n+i}^*$, $i = 1, 2$ are all skewed to the right, the medians may be better indications of performance of the NPI method. We also see that the mean, median, and standard deviation of $T_{\text{low},n+1}^*$, $T_{\text{up},n+1}^*$, $\Delta_{\text{low},n+1}$, and $\Delta_{\text{up},n+1}$ are all larger than the corresponding quantities at time $n+2$, which reflects that the NPI-based optimal replacement times adapt well to the process data.

Multiunit Maintenance Models

In multiunit systems, units may depend on each other economically, structurally, or stochastically, as described in the section titled “Model Characteristics”. Consequently, the optimal maintenance policy is not derived by considering each unit separately, and maintenance decisions are not independent. For such situations, we discuss group maintenance, repair/inventory, inspection/maintenance, and cannibalization models. For overviews of maintenance models for multiunit systems, see e.g. [4, 8–10].

Group Maintenance Models

When considering an infinite time horizon, group maintenance models can be divided into three categories [9]: (a) Group corrective maintenance models, (b) group preventive maintenance models, and (c) group opportunistic maintenance models.

Group Corrective Maintenance Models. In such models, units are only correctively maintained, and a failed unit can be left until its corrective maintenance is carried out jointly with that of other failed units, so this requires some redundancy to be available in the systems. If there exists economies of scale, simultaneous corrective repair is advantageous, but leaving units in a failed condition for some time increases the risk of costly production losses. The basic group maintenance model [9] for a system consisting of n identical parallel units assumes that (a) the number of failed units and the age of nonfailed units is always known; (b) repair results in an “as good as new” unit; (c) repairs can start at any time; (d) the functionality of the nonfailed units is not affected by a failed unit (no probabilistic dependency). The costs consist of two components, one concerned with loss of productivity at a rate $C_1(k)$ per unit of time when k units are down, the other related to the cost $C_2(k)$ of repair per unit when k units are in repair. The goal is to minimize the long-run expected costs per unit time. Several results have been presented for specific functions $C_1(k)$ and $C_2(k)$.

Group Preventive Maintenance Models. An important class of group preventive maintenance models is the class of *block-replacement models*, where a unit is replaced at failure *and* all units of the group are replaced simultaneously at times kT , $k = 1, 2, \dots$, independent of the system’s failure history.

Let F be the cdf of the failure time and $M(T) = E[N(T)]$ the expected number of failures in $[0, T]$, and assume that the corresponding pdf’s, f and $m(T)$, exist. The cost of corrective repair is c_f and the cost of the block replacement is c_b . For block-replacement policy with interval T over an infinite time horizon, using the renewal reward theorem, the long-run expected costs per unit time are

$$C(T) = \frac{c_f M(T) + c_b}{T} \quad (20)$$

If F is continuous, $C(T)$ has a minimum for $0 < T \leq \infty$. A necessary condition for a finite

value T^* to minimize equation (20) is $T^*m(T^*) - M(T^*) = c_b/c_f$ [2], and the corresponding minimal costs are $c_fm(T^*)$.

Example 4 (Block-replacement model) Suppose that a unit’s failure time has pdf $f(t) = \lambda^2 t e^{-\lambda t}$ with $\lambda = 0.1$, for $t \geq 0$, and let $c_f = 10$ and $c_b = 2$. The corresponding expected number of failures during $[0, T]$ is

$$M(T) = \frac{\lambda T}{2} - \frac{1}{4} (1 - e^{-2\lambda T}) \quad (21)$$

The optimal block-replacement time T^* is obtained by solving

$$\left(\frac{\lambda T}{2} + \frac{1}{4} \right) e^{-2\lambda T} = \frac{1}{20} \quad (22)$$

which yields $T^* = 14.97$ with $C(T^*) = 0.475$, so the optimal block-replacement policy is to replace a unit at failure, while also replacing all units at $15k$ for all $k = 1, 2, \dots$. The expected number of failures during each such 15-units interval equals 0.511.

The block-replacement model assumes a fixed group of units. Another group maintenance problem concerns the optimal grouping of the units for such cases, in which case the combinatorial aspects complicate the problem [9].

Group Opportunistic Maintenance Models. In opportunistic maintenance models, both preventive and corrective maintenance can be used to obtain economies of scale, with preventive maintenance possible if opportunities occur. In such cases, the unpleasant event of a failing unit may provide an opportunity for preventive maintenance of other units. Besides models where the process that generates opportunities depends on the failure process, models where these processes are independent have also been presented [40].

For a finite time horizon, dynamic group maintenance models are more appropriate. In such models, short-term information on deterioration of units or unexpected opportunities is taken into account. Dynamic models can be categorized according to *finite* or *rolling* time horizon [9]. In finite horizon models, it is assumed that the system is not used afterwards. Rolling horizon models also use finite horizons, but they do so repeatedly and based on a long-term plan: once decisions based on a finite

horizon are implemented, or when new information becomes available, a new horizon is considered and a tentative plan based on the long term is adapted according to short-term circumstances. Rolling horizon models aim to bridge the gap between finite and infinite time horizon models, while combining advantages of both [9].

Other Maintenance Models

Maintenance models for multiunit systems are difficult to handle mathematically, in particular, in case of stochastic dependence among the units. In such cases, few analytical results are obtainable on operating characteristics and optimal activities. Often, the only way to deal with such problems is by simulation or approximations. For some classes of models, some theoretical results have been presented.

1. Repair/inventory maintenance models

Most maintenance models discussed above assume that the replacement units are always available. However, in real life situations, availability of spare units is an important factor in determining an optimal maintenance policy for a system. Besides decisions on optimal times and levels of repair and replacement, other main decisions to be made include the decision on optimal times and levels of replenishment of spare units.

2. Inspection/maintenance models

In preparedness maintenance models, the current states of the units of the system are unknown unless an inspection is performed. Assaf and Shanthikumar [41] present an inspection/maintenance model considering a system consisting of N units, each having exponential failure time with constant rate. A failed unit can be repaired at any time, and a repaired unit is considered as good as new. It is assumed that the number of failed units is unknown, unless an inspection is carried out. Upon an inspection, a decision is required on whether to repair the failed units or not, based on the number of failed units in the system. The cost function consists of inspection costs, repair costs, and penalty costs associated with production losses due to failed units. Under the criterion of minimal long-run expected costs per unit time, they derived a necessary and sufficient condition for an optimal policy, together with its general form.

Barker and Newby [42] consider a multiunit system in which the deterioration of each component is modeled by a Wiener process. They derive an optimal inspection and maintenance policy for a model with two thresholds ξ and L ($\xi < L$), such that if the system's deterioration exceeds the first threshold ξ , maintenance is performed, while if it reaches the second threshold L , the system fails. The first threshold ξ ensures a minimum level of reliability.

3. Cannibalization models

In cannibalization models, units of the same type are used in different subsystems. Cannibalization simply involves interchanging units between subsystems, to increase the number of functioning subsystems, whenever some units in the system are inoperative. Such a replacement policy can be used when there are no spare units available.

There is a lot of ongoing research on maintenance models for multiunit systems, in particular because multiunit systems can be so complex that each model is system specific. For more information about maintenance models for multiunit systems, we refer the reader to the overview papers [1, 4–6, 8–10].

Repairable Systems Reliability

Models for repairable systems must describe the random occurrence of events in time. After a repairable system fails, it is repaired. Quite often, we ignore the repair time or we do not count the repair time as part of the cumulative operating time. The assumptions we make about the effect of a repair often dictate the type of model we choose. For example, if we assume (in addition to a few other technical assumptions) that the repair is minimal, that is, it brings the system back to the condition just before the failure, then we are led to the Poisson process. If we assume that a repair brings a unit to a like-new condition, then we are led to the renewal process (see **Extreme Event Risk; Mathematics of Risk and Reliability: A Select History**). Under the piecewise exponential process, a repair effects a change in the level of the intensity. This change could be positive, leading to a higher intensity and a shorter expected time to the next failure, or negative, leading to a lower intensity and a longer expected time to the next failure. For the modulated Poisson process model, the effect of a repair is somewhere between minimal repair (same-as-old) and the renewal process (same-as-new).

These models, together with statistical inference for them, are covered in more detail in the next sections.

The Nonhomogeneous Poisson Process

Let $N(t)$ denote the number of failures through time t , and more generally, let $N(a, b]$ denote the number of failures in the interval $(a, b]$, with similar definitions for $N(a, b)$, $N[a, b)$, and $N[a, b]$. Thus, $N(t) = N(0, t]$. Suppose we make the following assumptions about $N(\cdot)$:

1. $N(0) = 0$,
2. if $a < b \leq c < d$, then $N(a, b]$ and $N(c, d]$ are independent random variables,
3. there exists a function $\lambda(t)$ such that

$$\lambda(t) = \lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t] = 1)}{\Delta t}$$

4.
$$\lim_{\Delta t \rightarrow 0} \frac{P(N(t, t + \Delta t] \geq 2)}{\Delta t} = 0$$

When these assumptions hold, we say that the process is a nonhomogeneous Poisson process (NHPP).

A few comments about these assumptions are in order. The first assumption is basically for accounting; we begin with no failures. The second is called the *independent increments property*; the numbers of failures in nonoverlapping intervals are independent. The function $\lambda(t)$ in the third assumption is called the *intensity function*. This intensity function measures how likely failures are as a function of the cumulative operating time t . If $\lambda(t)$ is increasing, then we will have reliability deterioration; that is, we expect failures to occur more frequently. If $\lambda(t)$ is decreasing, then we have reliability improvement; that is, we expect failures to occur less frequently. The fourth assumption excludes the possibility of simultaneous failures. The four assumptions together imply that the number of failures in the interval $(a, b]$ has a Poisson distribution with mean $\int_a^b \lambda(t) dt$.

We often make assumptions about the functional form of $\lambda(t)$. One common assumption is that $\lambda(t)$ takes the form

$$\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1}, \quad t > 0 \quad (1)$$

This process is called the *power law process* (see **Product Risk Management: Testing and Warranties, Reliability Growth Testing**), or sometimes the Weibull process. The intensity function has the same form as the hazard function of the Weibull distribution, although the intensity function and the hazard function are conceptually different. Given data in the form of the successive failure times, we usually would like to estimate the parameters of the process, β and θ in the case of the power law process. Before proceeding with this, we must identify how data are collected. If the data collection stops at a predetermined time, then the data are said to be time truncated. If the data collection stops after a fixed number of failures, then the data are said to be failure truncated.

Inference for the NHPP: Failure Truncated Case

Suppose that we observe a repairable system whose failure times are governed by an NHPP with intensity function $\lambda(t)$. Let $T_1 < T_2 < \dots < T_n$ denote the (random) failure times measured from the initial startup of the system. The number of failures, n , is

predetermined. The joint probability density function (pdf) of the n failure times is

$$f(t_1, t_2, \dots, t_n) = \left(\prod_{i=1}^n \lambda(t_i) \right) \exp \left(- \int_0^{t_n} \lambda(t) dt \right) \quad (2)$$

For the special case of the power law process, where $\lambda(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta} \right)^{\beta-1}$, the joint pdf, which can also be viewed as the likelihood function, is

$$\begin{aligned} f(t_1, t_2, \dots, t_n | \beta, \theta) \\ = L(\beta, \theta) = \frac{\beta^n}{\theta^{n\beta}} \left(\prod_{i=1}^n t_i \right)^{\beta-1} \exp \left(- \left(\frac{t_n}{\theta} \right)^\beta \right) \end{aligned} \quad (3)$$

From this, the maximum-likelihood estimators (MLEs) are found to be

$$\hat{\beta} = \frac{n}{\sum_{i=1}^{n-1} \ln(t_n/t_i)} \quad (4)$$

and

$$\hat{\theta} = \frac{t_n}{n^{1/\hat{\beta}}} \quad (5)$$

There must be at least $n = 2$ failures in order for the MLEs to exist. For details of the derivation of the MLEs, see Crow [1] or Rigdon and Basu [2].

In the power law process, the parameter β determines whether the intensity is increasing (deterioration) or decreasing (reliability growth). If $\beta = 1$, then the intensity function is equal to the constant $1/\theta$ (independent of t). This special case is the homogeneous Poisson process. Confidence intervals and tests of hypotheses for β are based on the result that $2n\beta/\hat{\beta}$ has a χ^2 distribution with $2(n-1)$ degrees of freedom. A $100 \times (1 - \alpha)\%$ confidence interval for β is

$$\frac{\chi_{1-\alpha/2}^2(2(n-1)) \hat{\beta}}{2n} < \beta < \frac{\chi_{\alpha/2}^2(2(n-1)) \hat{\beta}}{2n} \quad (6)$$

Since $\beta = 1$ is the boundary between decreasing and increasing intensity functions, it is often of interest to see whether 1 is contained in this confidence interval.

Hypothesis tests for β can also be based on the pivotal quantity $2n\beta/\hat{\beta}$. To test $H_0 : \beta = \beta_0$ against the two-sided alternative $H_a : \beta \neq \beta_0$, we would reject the null hypothesis if

$$\hat{\beta} < \frac{2n\beta_0}{\chi_{\alpha/2}^2(2(n-1))} \quad \text{or} \quad \hat{\beta} > \frac{2n\beta_0}{\chi_{1-\alpha/2}^2(2(n-1))} \quad (7)$$

We are often interested in testing $H_0 : \beta = 1$ against the alternative $H_a : \beta \neq 1$.

For the failure truncated case, confidence intervals and hypothesis tests for θ can be based on the tables of Finkelstein [3]. The entries in this table were determined analytically, so the confidence intervals and critical regions should have the nominal level.

In the situation of reliability growth, the important quantity is frequently the value of the intensity function when the testing stops. If no further improvements are made to the system, it is reasonable to assume that the failure process will be a homogeneous Poisson process whose constant intensity is equal to $\hat{\lambda}(t_n)$, the value of the intensity when testing stops. The MLE of $\lambda(t_n)$ is

$$\hat{\lambda}(t_n) = \frac{\hat{\beta}}{\hat{\theta}} \left(\frac{t_n}{\hat{\theta}} \right)^{\hat{\beta}-1} = \frac{n\hat{\beta}}{t_n} \quad (8)$$

Rigdon and Basu [2] give tables for constructing a confidence interval for $\lambda(t_n)$.

Goodness-of-fit tests for the power law process can be based on one of two transformation of the failure times $T_1 < T_2 < \dots < T_n$. One is the ratio-power transformation

$$\hat{R}_i = \left(\frac{t_i}{t_n} \right)^{\hat{\beta}} \quad (9)$$

where

$$\bar{\beta} = \frac{n-2}{\sum_{i=1}^{n-1} \ln(t_n/t_i)} \quad (10)$$

is an unbiased estimator for β . The rationale for this test is based on the following result. If the failure times are governed by a NHPP with intensity function $\lambda(t)$ and mean function $\Lambda = E(N(t)) = \int_0^t \lambda(u) du$,

then

$$R_i = \frac{\Lambda(t_i)}{\Lambda(t_n)} = \left(\frac{t_i}{t_n} \right)^\beta, \quad i = 1, 2, \dots, n-1 \quad (11)$$

are distributed as $n-1$ order statistics from the uniform distribution on the interval $(0,1)$. Using the unbiased estimator $\bar{\beta}$ in place of β gives $\hat{R}_i$ as defined above. Once this transformation is made, any goodness-of-fit test for the uniform distribution can be applied. Crow [1] suggests, and gives tables for, the Cramér–von Mises test which has test statistic

$$C_R^2 = \frac{1}{12(n-1)} + \sum_{i=1}^{n-1} \left(\hat{R}_i - \frac{2i-1}{2(n-1)} \right)^2 \quad (12)$$

The other transformation that leads to a goodness-of-fit test is

$$U_i = \ln \left(\frac{t_n}{t_{n-i}} \right), \quad i = 1, 2, \dots, n-1 \quad (13)$$

Rigdon and Basu [2] show that $U_1 < U_2 < \dots < U_{n-1}$ are distributed as $n-1$ order statistics from an exponential distribution with mean $1/\beta$. After this transformation is made, any goodness-of-fit test for the exponential distribution with unknown mean can be based on the U_i 's. See Rigdon [4] for a comparison of various tests for testing the power law process using the U_i 's.

A Bayesian analysis can be conducted on the power law process. The process follows the usual Bayesian paradigm.

1. Choose a prior distribution for (θ, β) that reflects prior belief about the parameters.
2. Collect data.
3. Inference is based on the posterior distribution of (θ, β) .

Guida *et al.* [5], Calabria *et al.* [6, 7], and Bar-Lev *et al.* [8] presented the details of a Bayesian analysis of the power law process and gave guidelines on the selection of a prior.

As an example of the power law process, consider the data from Duane [9] that is given in Table 1.

The MLEs of the parameters are

$$\hat{\beta} = \frac{14}{\sum_{i=1}^{13} \ln \left(\frac{4596}{t_i} \right)} = 0.483 \quad (14)$$

Table 1 Failure times of aircraft generator^(a)

Failure number i	Failure time t_i
1	10
2	55
3	166
4	205
5	341
6	488
7	567
8	731
9	1308

and

$$\hat{\theta} = \frac{4596}{14^{1/0.483}} = 19.474 \quad (15)$$

Clearly, the times between failure are getting larger, indicating reliability improvement, so we would expect the estimate of β to be smaller than 1. Confidence intervals (95%) using the formulas from this section along with the appropriate tables are

$$0.239 < \beta < 0.723$$

and

$$0.21 < \theta < 161$$

Inference for the NHPP: Time Truncated Case

Suppose now that testing stops at a predetermined time t . Inference for this case is similar to the failure truncated case. For the failure truncated case, the number of failures n is fixed and the time when testing stops t_n is random. For the time truncated case, the reverse is true: the number of failures N is random and the time t when testing stops is fixed.

The likelihood function is

$$\begin{aligned} f(n, t_1, t_2, \dots, t_n | \beta, \theta) &= L(\beta, \theta) \\ &= \frac{\beta^n}{\theta^{n\beta}} \left(\prod_{i=1}^n t_i \right)^{\beta-1} \exp \left(- \left(\frac{t}{\theta} \right)^\beta \right) \end{aligned} \quad (16)$$

From this, the MLEs are found to be

$$\hat{\beta} = \frac{n}{\sum_{i=1}^n \ln(t/t_i)} \quad (17)$$

and

$$\hat{\theta} = \frac{t}{n^{1/\hat{\beta}}} \quad (18)$$

The number of failures must be $n \geq 1$ for the MLEs to exist. Conditioned on $N = n$, the statistic $2n\beta/\hat{\beta}$ has a χ^2 distribution with $2n$ degrees of freedom. This result leads to the confidence interval

$$\frac{\chi_{1-\alpha/2}^2(2n)\hat{\beta}}{2n} < \beta < \frac{\chi_{\alpha/2}^2(2n)\hat{\beta}}{2n} \quad (19)$$

Similarly, the null hypothesis $H_0 : \beta = \beta_0$ is rejected in favor of $H_a : \beta \neq \beta_0$ if

$$\hat{\beta} < \frac{2n\beta_0}{\chi_{\alpha/2}^2(2n)} \text{ or } \hat{\beta} > \frac{2n\beta_0}{\chi_{1-\alpha/2}^2(2n-1)} \quad (20)$$

The MLE of the intensity at the conclusion of the testing phase, that is, at time t , is

$$\hat{\lambda}(t) = \frac{\hat{\beta}}{\hat{\theta}} \left(\frac{t}{\hat{\theta}} \right)^{\hat{\beta}-1} = \frac{n\hat{\beta}}{t} \quad (21)$$

Bain and Engelhardt [10] discuss further the inference for the time truncated power law process.

Goodness-of-fit tests can be constructed in a manner analogous to the failure truncated case. The appropriate transformations are

$$\hat{R}_i = \left(\frac{t_i}{t} \right)^{\hat{\beta}} \quad (22)$$

and

$$W_i = \ln(t/t_{n-i+1}), \quad i = 1, 2, \dots, n \quad (23)$$

The Renewal Process

If the repair process is such that it brings failed/ repaired items to a like-new condition, then the times between successive failures should be independent and identically distributed (i.i.d.). If we

let $X_1, X_2, \dots, X_n$ denote the times between failure, then the failure times are

$$\begin{aligned} T_1 &= X_1 \\ T_2 &= X_1 + X_2 \\ T_3 &= X_1 + X_2 + X_3 \\ &\vdots \\ T_n &= X_1 + X_2 + \dots + X_n \end{aligned} \quad (24)$$

If we let $\Lambda(t) = E(N(t))$, as we did for the NHPP, then we can define

$$\mu(t) = \Lambda'(t) = \text{rate of change in expected number of failures} \quad (25)$$

The function $\mu(t)$ is called the *rate of occurrence of failures* (ROCOFs). (Note that for the NHPP, the ROCOF is equal to the intensity function. For the renewal process, the intensity function makes no sense, but the ROCOF does, and we will study its properties.) It can be shown [2] that if $g_k(t)$ is the pdf of T_k , then

$$\mu(t) = \sum_{k=1}^{\infty} g_k(t) \quad (26)$$

For example, if the times between failure are i.i.d. gamma random variables with parameters $\theta = 0.1$ and $\kappa = 20$, having mean $\mu = \theta\kappa = 2$ and variance $\sigma^2 = \theta^2\kappa = 0.2$, then the ROCOF function is as shown in Figure 1. The pdf's for the failure times $T_1 < T_2 < \dots$ are shown in Figure 1(a), and the ROCOF is shown in Figure 1(b). The ROCOF is initially very low because the system starts out with a brand new component that is unlikely (under this model) to fail early in its life. Around time $t = 2$ is when we would expect the item to fail for the first time, so the ROCOF is large there, after which it decreases. Figure 1(b) suggests that the ROCOF will bounce up and down around the times of the expected failures, but after a while, the randomness in the failure times will make the ROCOF nearly constant. This suggests the following result. (The proof is long and complicated, but is given in Rigdon and Basu [2].) For a renewal process with times between failures $X_1, X_2, \dots$, each a continuous random variable having support $[0, \infty)$ and having mean η and finite variance,

Figure 1 Pdf's and ROCOF for a gamma renewal process

$$\lim_{t \rightarrow \infty} \frac{\Lambda(t)}{t} = \frac{1}{\eta} \quad (27)$$

$$\lim_{t \rightarrow \infty} \mu(t) = \frac{1}{\eta} \quad (28)$$

Since, for the renewal process, the times between failures are i.i.d., analyzing data from a repairable system modeled by the renewal process is the same as inference for nonrepairable systems whose lifetimes are i.i.d.

The Piecewise Exponential Model

The piecewise exponential (PEXP) model was proposed by Sen and Bhattacharyya [11]. Under this model, the times between failure are independent exponential random variables, but each has a different mean, so times between failure are not i.i.d. Under their model, the mean of the i th time between failures is

$$E(X_i) = \frac{\delta}{\mu} i^{\delta-1}, \quad i = 1, 2, \dots \quad (29)$$

The parameter μ acts like a scale parameter, and the parameter δ measures the degree of deterioration. If $\delta = 1$, then the times between failure are i.i.d. exponential and therefore the process is the homogeneous Poisson process. If $\delta < 1$, then $E(X_i)$ is decreasing in i , indicating reliability improvement. If $\delta > 1$, then $E(X_i)$ is increasing in i , indicating reliability deterioration. Under the PEXP model, reliability improvement (or deterioration) is effected at the time of a failure, as compared to the NHPP where the reliability improvement (or deterioration) is continuous.

Inference for the PEXP can be found in Sen and Bhattacharyya [11] and Sen [12].

The Modulated Power Law Process

The modulated power law process (MPLP) is a compromise between the NHPP (same-as-old) and the renewal process (same-as-new) models. This model is a special case of the modulated gamma process of Berman [13] and was proposed as a model for the reliability of repairable systems by Lakey and Rigdon [14]. One way to develop the MPLP is to envision a power law process with parameters θ and β , except that a failure occurs not at every event in this power law process, but rather every κ th event, where κ is a positive integer. Under such a model, if $\beta > 1$, then there will be overall reliability deterioration, but after each failure, the subsequent repair would make the system better than it was just before the failure because the number of events would be reset to zero, and another κ events would be required before the next failure. Thus, a system can be deteriorating, but still be improved at the time of a failure/repair.

If the likelihood is developed under the above assumptions, it can be seen that this is a valid likelihood even when κ is not an integer. Another way of developing the MPLP (not shown here because it is rather complicated) does not make the assumption that κ is a positive integer, only that $\kappa > 0$.

Inference for the MPLP was developed by Black and Rigdon [15] and is summarized by Rigdon and Basu [2].

Inference for Multiple Systems

So far, we have assumed that inference has been for a single system. If there are multiple copies

of the system, the type of inference depends on the assumptions we are willing to make about the similarity of the systems. Here are a number of possibilities.

1. No assumptions

If no assumptions are made about the various systems, then data from each system should be analyzed separately.

2. All systems identical

If this is the case, then the likelihood is easily developed for most models described here. Crow [1] described how this is done for the power law process.

3. Systems with the same deterioration parameter, but possibly different scale parameters

In the context of the power law process, this would imply that all systems have the same β parameter, but different θ 's. This case was also described by Crow [1].

4. Systems with the same deterioration parameter, but different scale parameters that can be thought of as being selected from some joint (prior) distribution

Again, in the context of the power law process, the β parameter would be the same for all systems, but we would view $\theta_1, \theta_2, \dots, \theta_n$ as being a random sample (i.i.d.) from some distribution $g(\theta)$. At this point, we could apply an empirical Bayes method, or, if we place a prior on the parameters of $g(\theta)$ as well as β , we could apply a fully Bayesian analysis.

5. Systems with different deterioration parameters and different scale parameters, but each can be thought of as being selected from some (prior) distribution

For the power law process, this would mean that $(\theta_1, \beta_1), (\theta_2, \beta_2), \dots, (\theta_n, \beta_n)$ are selected from some (prior) distribution $g(\theta, \beta)$. Again, we could perform an empirical Bayes analysis or, if we place priors on all parameters, we would perform a fully Bayesian analysis.

Systems with Covariates

For systems whose failure times are observed along with covariates (or concomitant variables), we can use Poisson regression (*see Risk from Ionizing Radiation; Reliability Growth Testing; Cohort*

Studies; Repeated Measures Analyses; Competing Risks) to study the relationship between these covariates and the intensity function. Lawless [16] suggested a proportional intensity model (analogous to the proportional hazards model) that has the form

$$\lambda_{\mathbf{x}}(t) = \lambda_0(t)g(\mathbf{x}; \beta), \quad t > 0 \quad (30)$$

Here $\mathbf{x}$ is a vector of covariates and β is a vector of parameters. The function $\lambda_0(t)$ is called the *baseline intensity*. Since $\lambda_{\mathbf{x}}(t)$ must be a positive quantity, we require that $g(\mathbf{x}; \beta) > 0$ for all $\mathbf{x}$. A convenient and flexible choice for $g(\mathbf{x}; \beta)$ is

$$g(\mathbf{x}; \beta) = \exp(\mathbf{x}'\beta) \quad (31)$$

Lawless [16] considered a number of cases. If $\lambda_0(t)$ is an arbitrary function, then the method is called *semiparametric*. If $\lambda_0(t)$ has a parametric form, with some unknown parameters, then the method is called (fully) parametric. A common form for $\lambda_0(t)$ is the power law intensity function $\lambda_0(t) = \frac{\beta}{\theta} \left(\frac{t}{\theta}\right)^{\beta-1}$. Lawless also considers cases where there are random effects. He derived the likelihood equations for a number a number of different cases. Ciampi *et al.* [17] have developed a computer program to find the maximum-likelihood estimates of the regression parameters β and the parameters of the baseline intensity function.

Summary

Various models for the reliability of repairable systems have been discussed. Usually, the assumptions we make about the effect of a repair dictate the type of model that is selected. For analyzing multiple systems, the assumptions concerning the similarities of the various copies of the system lead us to a method of data analysis and inference. There are many other models for repairable systems. Ascher and Feingold [18] discusses a number of models that have not been covered here.

Repeated Measures Analyses

Repeated measurements occur frequently in a variety of disciplines [1–4]. Repeated measures data emerge in studies where the same response variable is recorded on each subject under two or more conditions or occasions. They can be collected from experimental studies (e.g., controlled clinical trials) *see* **Randomized Controlled Trials** or from observational studies (e.g., epidemiological cohort studies; *see* **Cohort Studies**), either prospectively or retrospectively (e.g., using medical records).

Repeated measurements in risk assessment studies include profit and loss, environmental consequences, medical outcomes, and risk perception data [5]. Proper analysis of repeated measures risk data can help decision makers understand the impact of uncertainty and the consequences of different decisions (*see* **Scientific Uncertainty in Social Debates Around Risk**). For examples, repeated measures analysis has been applied in comparative risk assessment of environmental risk [6] and in the study of assessing longitudinal changes in mammographic density associated with breast cancer risk [7].

Repeated measurements can be quantitative or categorical, univariate or multivariate. In repeated measures experimental studies, the subjects are often assigned to the competing treatment groups using *randomization* procedures. The treatment for any particular group of subjects might remain constant throughout the study, or vary from one occasion to another, as in the case of a *crossover design*. Repeated measures data often arise in longitudinal studies where the measurements are made at different time points, and the number and the spacing of the repeated measurements may vary from one subject to another, consequently, resulting in unbalanced data. The repeated measures data may be unbalanced because of the study design or because of data which is unintentionally missing. Missing data are very common for studies involving humans since it is often difficult for every subject to follow an exact schedule.

The repeated measures design provides opportunities for investigators to examine the pattern of response variable under different measurement conditions or occasions, to understand the relationship between repeated outcomes and covariates, and to

discern the dependence pattern among the repeated measurements. A special feature of repeated measures data is that measurements from the same unit are usually correlated, and thus statistical analysis often requires assumptions concerning the within-subject correlation. The analysis methods often differ across disciplines, such as between medicine and psychology [2], owing to various assumptions and conventions, different study objectives and designs, quantitative or categorical responses, and different approaches to dealing with missing data [8].

There have been many recent advancements with new interest in analysis of repeated measures. Analytical approaches for repeated measurements have been developed ranging from the simple to the complex. This paper provides a review of the analysis methods for repeated measures, including simple graphic display techniques, univariate summary methods, analysis of variance for balanced normal responses, parametric random-effect approaches, marginal generalized estimating equation methods, and modern semiparametric and nonparametric approaches. For brevity, we focus on longitudinal studies. For interested readers, sources for more technical details and theoretical developments are excellent monographs by Crowder and Hand [9], Lindsey [10], Diggle *et al.* [11], Davis [12], Little and Rubin [8], Ruppert *et al.* [13], Fitzmaurice *et al.* [14], and many others.

Data Visualization and Graphical Display

Graphical display techniques are useful for investigators to examine and visualize important patterns hidden in the data [2]. While exploring repeated measures data, an effective graphical display may reveal both cross-sectional and longitudinal patterns. Some useful guidelines for exploring repeated measures data have been suggested in Diggle *et al.* [11]. Next, a few techniques for graphical display are illustrated using some real data examples.

Example 1 Vitamin E and weight growth of guinea pigs: Crowder and Hand [9] discussed a study of the effects of various doses of diet supplement vitamin E on the growth of guinea pigs. A total of 15 guinea pigs were randomly assigned to control, low dose, or high dose groups. The animals were given growth-inhibiting substance during week 1 and then vitamin E diet interventions were initiated at week 5. Body-weight measurements of each animal

Figure 1 Box plots of body weights of guinea pigs for various Vitamin E dose groups at different time points

were made at the end of weeks 1, 3, 4, 5, 6, and 7. Box plots of the distribution of the measurements for each treatment group at each time point are presented in Figure 1. The side-by-side box plots at a specific time point show the cross-sectional differences of treatment groups; at the six time points, the three treatment box plots display the longitudinal pattern of body-weight growth. The box plot is effective and convenient to present the simple five-number summaries of quantitative data. It can be used in almost any available statistical package and also can give the indication of outliers (e.g., using circles) as illustrated in Figure 1.

Example 2 Halothane and blood pressure of rats with heart attack induction: Crepeau *et al.* [15] described a study on the effect of halothane on responses to irreversible myocardial ischemia and subsequent infarction. The study measured the blood pressure of 43 rats exposed to different concentrations of halothane (0, 0.25, 0.5, and 1%) after inducing heart attacks. The repeated measurements were observed at nine fixed time points, with some missing data. Using the available data, the averages of the blood pressure at each time point were calculated for four of the treatment groups; the results are presented in Figure 2. The curves of average blood pressure in different concentration groups are compared, and it is evident that the group with the

Figure 2 Mean profiles of blood pressure for four groups of rats treated with different doses of halothane

highest concentration of halothane shows the lowest blood pressures. However, one should be cautious that the values of average blood pressures in Figure 2 are calculated using the completely observed data only, and thus, such analysis may be biased (see more discussion in the section on missing data).

Example 3 Auranofin and self-assessment of arthritis: Fitzmaurice and Lipsitz [16] described a randomized trial on the effects of auranofin for patients with arthritis. A total of 51 patients were randomized into a treatment group or a placebo group. Each patient had at most five binary self-assessments on arthritis status (poor = 0, good = 1). The measurements were scheduled at baseline and subsequent weeks 1, 5, 9, and 13. In the treatment group with auranofin, the treatment changed from placebo to auranofin from week 5, and the placebo group remained on the same placebo treatment throughout the study. Because the response variable of self-assessment is categorical, the outcomes at each time point for each group are summarized using the proportion of good self-assessments, and the summary is presented using bar plots. In addition, twice the standard errors of the proportions are plotted to show variability of the proportions. In Figure 3, the side-by-side bar graphs show how the proportions of patients with good arthritis self-assessments vary over the five occasions, and different groupings of bars highlight the differences in male and female patients in the treatment groups.

Figure 3 Bar plots of proportions of self-assessments of arthritis patients

Univariate Summary Methods

In some cases, a simple and effective way to explore repeated measures data is to condense repeated measurements into some summary measurements, and then to model each summary variable (e.g., mean, median, range, change, or slope). This approach is also called *two-stage or derived-variable analysis*. The major task of this approach is to select one or more powerful and representative summary statistics to best characterize the main features of repeated measurements. Matthews *et al.* [17] provide a list of potentially useful summary measures according to the study objectives. For example, in the case of *crossover* studies, the average of two measurements may be used to determine the better order of administration of treatments. In the case of longitudinal data showing a linear trend, the individual intercept and slope may be representative of overall information in the data. One may fit a separate regression model using each individual's data, and the resulting estimates can be used as the derived variables for further analysis. In addition, this approach suggests the idea of using subject-specific random effects to explain the heterogeneity across the subjects (see the section

titled “Mixed-Effects Models”). The use of summary measures in the analysis of repeated measures data has several advantages as discussed in [2, 17]. However, the derived-variable method can be inefficient with highly unbalanced data and unfeasible when the covariates of interest change over measurement occasions.

Methods for Balanced Repeated Measures Data

Traditional multivariate methods, such as Hotelling T^2 and profile analysis can be used to analyze balanced repeated measures data if they are normally distributed (or after appropriate transformations). The Hotelling T^2 , an analog of univariate t -test, can test whether mean vectors are different between two groups. The multivariate normal distribution with an unstructured covariance matrix is a common method for modeling the joint distribution of repeated measures, especially in modeling growth curves and in psychology [18, 19]. The unstructured multivariate approach does not require any assumption on the covariance matrix at the cost of many degrees of

freedom in estimating covariance parameters. When the dimension of multivariate data is large, this can lead to low power to detect mean differences of interest.

Another proposal for modeling correlated multivariate Gaussian responses is the multivariate analysis of variance (MANOVA). The MANOVA is a multivariate analog of univariate ANOVA, and assumes an additive model where the response variable is related to a set of discrete covariates and the subject-specific random effects. Thus, the models assume a structured covariance matrix, in which the correlation among repeated measurements is assumed to attribute to a subject-specific random effect. The MANOVA models focus on comparing mean responses of units along different measurement occasions.

When normality of the repeated measures data is not assumed, nonparametric methods and other techniques may be used. Nonparametric alternatives that require less model assumptions include the Wilcoxon signed-rank test for the case of two repeated measures per subject and the Friedman test to analyze the treatment effect in the randomized complete block design. Also, it is practically rare to find balanced data sets in longitudinal studies and the response variable can be continuous or discrete. Therefore, it is necessary to use some alternative techniques that are essentially regression models to handle unbalanced data and relax distributional assumptions.

Methods for Unbalanced Repeated Measures Data

Unbalanced repeated measures data arise when the number of repeated measures per subject is not constant and/or the measurement timing varies across subjects. In addition, the response variable can be either continuous or categorical, and the explanatory variables can be either time independent (e.g., baseline) or time dependent. Various extensions of the univariate *linear regression models*, *generalized linear models*, and *quasi-likelihood* methods have been proposed for the analysis of unbalanced repeated measurements. In this article, we will classify the analysis methods for unbalanced data into three categories [20]—mixed-effects models, marginal models, and transition models.

Mixed-Effects Models

One can view the mixed-effects model as a generalization of the univariate (generalized) *regression model* with correlated errors. The linear mixed-effects model allows explicit specifications on the association between the responses and population-level factors and subject-specific covariates. It can accommodate complex measurement patterns in the observation of repeated measures. In mixed-effects models, the subject-specific random-effects account for between-subject heterogeneity. More specifically, let $\mathbf{Y}_i = (Y_{i1}, \dots, Y_{im_i})$ be the response of subject i at m_i measurement occasions, $i = 1, \dots, n$. The mixed-effects model is specified as follows. Given a $q \times 1$ vector of the subject-specific random effects, b_i , the conditional mean of the response Y_{ij} at the j th occasion, is given by

$$g\{E(Y_{ij}|b_i, X_{ij}, Z_{ij})\} = \beta'X_{ij} + b_i'Z_{ij} \quad (1)$$

where $g(\cdot)$ is a monotone continuous link function, and β denotes a $p \times 1$ vector of fixed effects. The covariates of interest, X_{ij} and Z_{ij} , can be identical, overlapped, or mutually exclusive. In addition, the responses are assumed to be independent, conditioning on the random effects. The random effects, b_i , are assumed to be independent and identically distributed with a parametric distribution function.

For continuous responses, the link function is often set to be an identity function and $\text{Var}(Y_{ij}|b_i) = \sigma_e^2$. Thus, equation (1) becomes a linear mixed-effects model [21–23]. Assuming normality for the random effects and error terms, the likelihood function for Gaussian repeated measures data can be expressed in an explicit form. One can estimate the regression parameters and covariance parameters using the *maximum-likelihood* (ML) method or the restricted maximum-likelihood (REML) approach [21, 24]. For general categorical responses with nonlinear link functions, evaluation of the likelihood requires numerical methods in most cases (e.g., see Gaussian quadrature method or the first-order Taylor series approximation). Breslow and Clayton [25] proposed an approximation to the integrand so that its integrals of the likelihood function have closed forms. This method gives effective estimates of the fixed effects. However, it can yield biased results for the parameters associated with the distribution of random effects.

Marginal Models

When the objective of the study is focused on the marginal, population-averaged associations between responses and covariates, marginal models can directly address this aim. The generalized linear regression models specify the marginal mean as

$$g\{E(Y_{ij}|X_{ij})\} = g\{\mu_{ij}\} = \beta'_M X_{ij} \quad (2)$$

where $g(\cdot)$ is a known link function, and β_M characterizes how the cross-sectional response distribution depends on the covariates. In this context, the marginal regression coefficients are of primary interest. Semiparametric and parametric approaches have been proposed for the inference of these marginal models.

The Generalized Estimating Equations Approach.

Liang and Zeger [26] proposed a generalized estimating equation (GEE1) approach, which can be viewed as a multivariate generalization of the quasi-likelihood estimation method. The GEE method is a flexible and powerful tool in the analysis of repeated measures data, especially for categorical responses. The method is semiparametric in nature because it does not require a full specification of the joint distribution of the multivariate responses. The approach yields consistent estimates as long as the marginal mean model is correctly specified, regardless of specifications of the within-subject associations.

More specifically, the generalized estimating equation for β_M is specified as

$$U(\beta) = \sum_{i=1}^n \left(\frac{\partial \mu_i}{\partial \beta_M} \right)' [V_i(\alpha)]^{-1} (\mathbf{Y}_i - \mu_i) = 0 \quad (3)$$

where $\mathbf{Y}_i$ and μ_i are vectors consisting of corresponding components of Y_{ij} and μ_{ij} , $V_i(\alpha) = \phi A_i^{1/2} R_i(\alpha) A_i^{1/2}$, ϕ is a variance scale parameter, $R_i(\alpha)$ is a working correlation matrix, and A_i is a diagonal matrix consisting of marginal variance of Y_{ij} . Liang and Zeger [26] proposed to replace ϕ and α by their consistent estimates and developed an iterative algorithm to estimate β_M . The GEE is constructed on the basis of the first sample moment, so that the inferences about β_M are insensitive to the specification of V_i . Several choices for the working correlation matrix have also been suggested by Liang and Zeger [26]. The simplest choice is the independent working correlation matrix. It works reasonably

well when the number of subjects is large relative to the number of repeated observations since the correlation influence can be small in this situation. Other choices include exchangeable working correlation matrix, the first-order autoregressive model, and unstructured model.

Zhao and Prentice [27] extended the original GEE method to allow the joint estimation of the mean and covariance parameters (GEE2). When both the marginal mean model and covariance structure are correctly specified, the GEE2 approach leads to more efficient estimates; otherwise, it can be biased.

The Marginalized Likelihood Approaches

The GEE method described above has some advantages in robustness since it does not require the correct specification on the within-subject correlations. But sometimes, its efficiency can be a concern. The marginalized likelihood approaches not only specify the marginal mean regression model, similar to the one in the GEE method, but also specify the joint multivariate distribution through higher-order assumptions [28–32]. Therefore, one can carry out efficient likelihood-based inference and individual level prediction for repeated measures data when the target of inference is on the marginal, population-averaged covariate effects. In addition, the marginal inference is insensitive to the higher-order model misspecifications [33]. However, the marginalized likelihood approaches can be computationally intensive owing to the iterative conversion between the marginal models and higher-order models, and the evaluation of the likelihood function.

Semiparametric Regression Models

The models described above assume that the mean model has a parametric linear regression expression. In practice, however, the parametric linear assumption may be restrictive, and the analysis is susceptible to misspecifications of the parametric model. In the semiparametric and nonparametric regression models of Lin and Ying [34] for continuous longitudinal data, the marginal means of continuous responses are directly modeled using a semiparametric regression model,

$$E\{Y_i(t)|X_i(t)\} = \alpha_0(t) + \beta' X_i(t) \quad (4)$$

where $\alpha_0(t)$ is an unspecified baseline function. The model does not require any assumption on the stochastic distribution of the responses and has also been further generalized to accommodate *time-varying* coefficients, i.e., $E\{Y_i(t)|X_i(t)\} = \alpha_0(t) + \beta'(t)X_i(t)$. In addition, the method of Lin and Ying can allow the recurrent observation process to be dependent on covariates that can be incorporated using a semiparametric multiplicative rate model [35]. Discussions on efficient semiparametric marginal estimation models for longitudinal data can be found in [36–38]. Other general semiparametric regression models for various types of repeated measures data are discussed in Ruppert *et al.* [13].

Transition Models

Transition models for repeated measures characterize the conditional distribution of each response Y_{ij} as an explicit function of covariates and the history of $(Y_{i1}, \dots, Y_{i(j-1)})$. For example, a conditional generalized linear model can be specified as

$$\begin{aligned} g\{E(Y_{ij}|Y_{i1}, \dots, Y_{i(j-1)}, X_{ij})\} \\ = \beta'X_{ij} + \gamma'f(Y_{i1}, \dots, Y_{i(j-1)}) \end{aligned} \quad (5)$$

where $f(\cdot)$ is a known function of the past observations. One useful transition model is the k -order Markov model, where the conditional distribution of the current response depends only on the k prior observations. Tsay [39] proposed the Markov linear model for continuous responses. For binary responses, Korn and Whittemore [40] and Zeger *et al.* [41] proposed a logistic first-order Markov chain model. Zeger and Qaqish [42] developed a first-order Markov chain Poisson model for count data. Transition models are similar to the *autoregressive* models for *time-series* data. Note that repeated measures data usually consist of a large number of shorter sequences, whereas time-series data typically arise from a single or a few long extending sequences.

Comparisons among the Three Types of Models for Unbalanced Data

Under the situation of linear models for continuous responses, the above-discussed three classes of models can yield the same type of interpretation of the regression coefficients. Coefficients from the linear

mixed-effects models and the transition models can both give the marginal interpretations. However, in the case of categorical response with a nonlinear link function, these three models yield different interpretations for the regression coefficients such that each may be suitable for a specific objective.

The regression coefficients of the mixed-effects models have a subject-specific interpretation; that is, the conditional effects of the explanatory covariates conditioning on the subject-specific random effects. This type of model is more appropriate when the scientific focus of the repeated measures study is on the individual's responses. Nevertheless, it can be awkward for interpreting the population effects. For example, it can be difficult to interpret gender difference given the same values of the random effects, because it is unnatural to assume a man and a woman have the same values of the random effects.

The regression coefficients in transition models have an interpretation of the effects of covariates adjusted for the individual's response history. The transition models are more appropriate when the target of inference is on the stochastic process of the repeated measurements given the covariates and the history, but they can be inappropriate for the estimation of population-level and time-independent covariate effects.

In contrast, marginal models yield interpretations of the regression coefficients as the population-averaged effects. They are suitable for studies focusing on the population-level inference, such as comparing treatment groups. In addition, marginal models separate the specification for marginal mean regression models from the assumption on the associations among repeated measures. Hence, the interpretation of regression parameters is invariant with respect to different assumptions for the within-subject correlations. On the other hand, mixed-effects models and transition models specify the covariate effects and within-subject association in one model. In summary, it is useful to consider the differences among various models when choosing appropriate models for practical applications.

Analysis Methods for Missing Data

Repeated measures data are often incomplete for reasons such as scheduled measurements not being taken or not being available. Missing measurements in the

repeated measures data result in unbalanced data and entail technical difficulties to statistical analysis. The missing pattern can be classified into two broad groups as monotone missing and intermittent missing. If the missingness occurs in the monotone fashion, all subsequent observations would be missing, e.g., patient dropouts or death in clinical trials. Intermittent missing patterns include situations where the subjects return to the study after missing one or more scheduled observations. It is also important to raise the deeper conceptual questions on the reasons for the missing measurements. The missingness is often classified into three categories: missing completely at random; missing at random; and nonignorable missing as discussed in Little and Rubin [8].

The simplest analysis to handle repeated measures data with missing measurements is to only use the subjects with complete observations. However, this approach obviously can waste a large amount of information by discarding all incomplete observations. More seriously, it may potentially introduce bias if the missing mechanism is related to the responses. Another way to handle repeated measures data with missingness is the *last observation carried forward*, which is an imputation method by extrapolating the last observed measurements for all subsequent missing observations. This method is primarily used for testing the null hypothesis of no difference between treatment groups. It is argued that, under the null hypothesis, the subsequent extrapolation of the last observed values represents the inherent feature of random outcome of a given subject and thus, the test remains valid without requiring an explicit modeling assumption.

Most statistical methods remain valid when data are missing completely at random. Thus, it is of interest to test whether the data missing mechanism is completely at random. Diggle [43] proposed a method to test for monotone dropout completely at random. Chen and Little [44] developed tests for general missing completely at random. Likelihood-based inference approaches without modeling assumptions on missing mechanism are usually valid for data missing at random. However, statistical inference for nonignorable missing data is a challenge. Indeed, to obtain valid estimates about the complete responses, the relationship between responses and the missing mechanism must be specified. One must also note that any assumption made about nonignorable missingness is, in general, unverifiable using the observed

data. Without external information about the underlying missing reasons, the observed data provide no information for determining the validity of assumptions on nonignorable missing data. In the literature, three broad classes of models have been extensively discussed for repeated measures with nonignorable missing: selection models [45–47]; pattern-mixture models [48–50]; and latent variable models [51–53]. Some authors have also provided excellent overviews of recent work in this area [54, 55].

Statistical Software and Summarizing Remarks

For the analysis of repeated measures data, most of the currently available statistical software are adequate for simple graphical displays, analysis at individual time points, or using the summary statistic approach. Also, a large number of statistical packages have the capacity of performing the analysis of variance procedures, the mixed-effects model, and the generalized estimating equation model. It is worth mentioning that, recently, more and more statistical algorithms developed using “R” are freely available, providing the capacity to fit complex statistical models that allow for missing data and a variety of covariance structures [56, 57].

In summary, repeated measures arise frequently in many studies. Many methods for statistical analysis have been suggested including simple *t*-tests at each separate occasion, summary statistics, multivariate analysis of variance, parametric random-effects methods, generalized estimating equation approaches, or modern semiparametric and nonparametric models. The field is still evolving rapidly, however, it is safe to say that no single “optimal method” is applicable to all cases, simply because such repeated measures can be collected in many settings, with various study designs, and different aims. A number of analysis methods are discussed in this article, but a thorough review of the field is beyond the scope of this article. More references and technical details can be found in the many cited recent monographs and review papers.

MENGLING LIU AND YONGZHAO SHAO

Risk and the Media

The news media helps to shape public discourse surrounding risk issues by its own portrayal and representations of risks and uncertainties in news stories [1]. The public typically receives a variety of information through the news media – from environment and health risks and benefits, to advances in science and technology, and government policy decisions. At the same time, the media plays a complex role in the portrayal of risks and associated uncertainties [1–4]. Media reporting can influence the process by which a risk becomes more prominent or “amplified” by the public [3, 5]. Often as the frontline popular communicators of science, the media takes the necessary scientific information from the risk assessors and makes it accessible to the public [5]. Exploring the processes of how the media communicate and present risk information is important (*see Considerations in Planning for Successful Risk Communication*).

Shaping Agendas: How the Media Report Risk Issues

Prominently covered health issues regularly include discussions of risk [6], whereas a “risk” category is often incorporated when reporting environmental issues [7]. When both health and environmental risks are involved, these typically appear as front page news [8], elevating the importance of the risk(s) being presented. However, little is known about how the media selects and structures risk stories and how individuals use these messages to form their own opinions [7].

The mass media has been recognized as one of the key players (and gatekeepers) that help build [9] and shape a policy agenda for those issues that gain public attention and those that do not [10]. Its influence is often short-lived because the media frequently jumps from issue to issue [11]. Issues being presented in the media have ways of grabbing public attention when they may have been virtually ignored weeks or months before. Focusing events (e.g., *via* public opinion polls, media attention to a risk event, etc.) can prompt an issue to move higher up a political agenda, or at least register on the public or political “radar screen”, for a short period of time [12]. Often, it is through the use of language or symbols that

issues can be manipulated on or off the agenda [13]. A common finding in agenda-setting research is that “issues emerge and recede from the public agenda without important changes in the nature of the issues themselves” [12, p. 47]. In other words, even when the issue is not resolved, the attention dedicated to the issue, by the media, the public, or decision makers, may wane.

The media, government (represented by policy agendas), and public agendas have varying influences over one another. The extent of media influence on public opinions can be assumed by the length of time that an issue appears on the media’s agenda. The longer the issue appears in the media, the more likely it is that the public views it as an important issue. Although the public has some influence over what appears on the policy agenda, the converse is less true. The government’s influence over the public has long been noted as coming *via* the media [14]. However, in light of technological advancements, like the internet, the public can now be directly informed of policy decisions, without interpretation from the media. In this manner, the government has developed some influence on the public’s agenda.

Examining of the agenda-setting role of the mass media has been documented in the literature, most notably in political studies about voter preferences during elections (e.g. [15]), in studies of environment and/or health risk issues (e.g. [6, 16, 17]; *see Environmental Health Risk*), and in edited volumes on the role of the media in communicating risks and science to a public audience (e.g. [18]). In summarizing a 25-year evolution of agenda-setting issues, McCombs and Shaw [15] argue that a common thread within these different studies exists: the media not only tells us *what to think about* but may also influence *how we think about it*. In reporting some components of a story over others, journalists and editors portray the *newsworthiness* of a story to the public [19]. The media’s tendency to present the novel or dramatic [3, 5, 7, 16] over the more common (and often more serious) risks [3] only serves to further distance expert *versus* lay understandings of risk issues.

Slovic [2] indicates that few journalists have the scientific background required to make sense of the wealth of data that is available to them to understand risks. This can result in scientific uncertainties or limitations being inadequately communicated to the public, particularly when “quick” answers are required

[20]. Few studies have been done to determine the extent to which journalists understand the science behind a risk, or probability theory, which is the process by which risks are assessed [7]. As the public seeks out additional information, especially about health risks, it is possible it will become more media-dependent [14]. This is particularly dominant if its only “understandable” source of information is through the media [17]. Dunwoody and Peters [16] argue that when specifically looking at risk research, the media reflects less of what the “experts” consider objective research, but more of the political and social processes that highlight what is occurring at that time. This may have a possible agenda-setting influence based on what the media is presenting [21].

The Media as Amplifiers of Risk

Public perception or understanding of a specified risk is influenced by both media presentation of a risk and how dependent the public is on the media for information. Kasperson and colleagues [3] argue that the media act as amplifiers of risk, or “stations”, constructing and communicating information about that particular risk. First introduced in 1988 by Kasperson and colleagues, the social amplification of risk framework is designed to bring together risk perception and risk communication research [3].

Bennett [22] summarizes the key “triggers” that will capture media (and hence public) attention: blame, conspiracy stories, identifiable victims where many people are exposed, embroiled in conflict, links to other high-interest stories, has a high signal value (portends future ills), is strongly visual, and may be linked to sex or crime. These triggers could amplify a risk, particularly when more than one is present.

The amplification causes a rippling effect, where the risk may be augmented throughout society on the basis of how stories are presented. The media serves as a channel of communication, whereby the information about that risk, and thus its mediated interpretation, flows through [3]. Frewer [23] suggests the framework can also indicate why a small risk with little physical impacts attracts substantial attention when a larger risk with considerable impacts does not. Frewer [23] argues that the extent of media influence over the amplification, or the rippling process, may be related to how the public trusts the information source and the information itself. Thus, greater trust in the source can intensify believability

of the nature of risk, whereas less trust in the source can attenuate the belief about the hazard.

The way in which risk *events* are covered by the media is equally important. Termed as *what-a-story* [24], it occurs when an issue is so consequential, dramatic, and unusual that media outlets drop everything else to report on this event [25]. When the story breaks, it is broadcast throughout the region, state, and possibly country. “What-a-story” events often contain the elements needed to create a satisfying media story – villains, victims, heroes, and tragic circumstances – where one can imagine the verbal and nonverbal gestures and excitement that accompany the announcement of a story in a newsroom [24]. When a major risk issue occurs, the typical reporting pattern is one of greater coverage within the first 10 days [26]. The media tends to provide blanket coverage of the event, such as was found during the media coverage of the Walkerton, Ontario, Canada, contamination of local drinking water supplies that resulted in 2300 people becoming ill and seven deaths, in May 2000 [27]. This initial reporting period plays an important role in establishing a mental image of the risk issue for the general public [26], and could also serve to amplify risk. After this 10-day period, the number and frequency of stories typically drops.

The Use of Frames by Journalists

Frames provide a way of packaging a story so that specific themes or subject matter are emphasized to help define what the issue is really about [28]. The ways in which stories are framed may have an impact on the ways in which the public interprets the story [29]. Frames act as a powerful agent in manipulating information that is disseminated to the public. It is important that risk assessors or risk managers are aware of how their communication of a risk may influence the story frames used by the media.

For example, Leiss [30] found that the initial frames used to describe dioxins (*see Dioxin Risk*), as chemical warfare, back in the early 1970s, put dioxins at the foreground of public attention as a very harmful substance. Over time, this initial framing remained dominant in media stories about dioxins forming a boundary around what aspects are (or not) discussed [31]. A study conducted by Singer and Endreny [32] illustrates that a rare hazard is more newsworthy than a common hazard; a new hazard is more newsworthy

than an old one; and a dramatic hazard that kills many people mysteriously is more newsworthy than one of chronic or familiar illnesses. Similarly, Driedger and Eyles [31] argue that in order to generate a sense of “outrage” and to receive the greatest level of resonance, for a risk story, they must be framed both at the macro level (statistical risk) and at the micro level (individual level).

Both Dunwoody [7] and Potter [33] suggest several modalities by which journalists frame their stories. Dunwoody [7] indicates it is not the job of the journalist to educate the public. A journalist’s role is to inform, but not necessarily with comprehensive details. Historically, journalists have presented the “facts” with very little interpretation about what these facts mean. It was only in the twentieth century that presenting the facts was considered insufficient: to provide the bigger picture facts needed to be contextualized or interpreted for public consumption [34]. Potter [33] suggests that journalists frame their stories so that they are easily recognizable to their audience members. By making the necessary, and purposeful, selections of the information they wish to present, journalists may be able to manipulate the readers to incorporate only the presented items in their understanding of the issue.

Framing is not without its problems. Selection processes limit precise accounts of a risk, thereby making it difficult for the public and decision makers to plan on how to deal with the risk. Social scientists have documented media coverage being often at odds with the scientific assessments of risk. Slovic [2] indicates that content analysis of media reporting on specific hazards has shown a great deal of misinformation and content distortion. As such, the public receives information that is not completely value-free or information rich. For example, there have been several studies concerning media coverage of the accident at Three Mile Island. Repeated stories about Three Mile Island redirects public attention away from competing news stories [5, 35]. At the same time as Three Mile Island, one of the worst airline accidents in American history (at that time) occurred, killing 274 people. Media focus was on Three Mile Island [35], mobilizing fears about risks associated with nuclear power and the possibility of similar nuclear accidents occurring more frequently elsewhere in the country [5].

Summary

It is important for risk assessors to be aware of how risk estimates may be presented in the news. Media outlets (reporters, editors, and owners) play a role in building and shaping public and policy agendas. Media presentations of risk could influence how risk issues are amplified in a public domain. As a result, it is important for risk communication strategies to have a user-based approach such that decisions are made to present what needs to be communicated to address lay concerns based on an understanding of what knowledge is held by a public audience. In other words, it is important to determine what a public knows and balance this against what a communicator needs them to know – not necessarily what a communicator wants to tell them.

Risk Attitude

Risks Everywhere

Whether it be endogenous or exogenous (as in natural risks), risk may be more or less accepted or abhorred by individuals and populations. History offers innumerable examples where risk is well accepted and even searched for: Egyptians not only knew of the floods near the Nile, but also knew that they would have better agricultural crops there and *intentionally* settled in the area close to the river. Our technological and financial civilization does the same by *intentionally* looking for new products and/or processes in the hope of increasing welfare, but knowingly facing possible adverse consequences in doing so. *Risk attitude* is therefore a fundamental concept, characterizing the degree to which the individual or the organization or a society at large accepts to face a probability mass of adverse consequences in view of desired potential effects. A similar point can be made about the degree of protection we may want to seek against some risk *imposed* on us by natural or social events over which we have no control. As a result, a “risk situation” involves four factors: (a) consequences, (b) their probabilities and distribution (c) individual attitudes preferences, and (d) collective and sharing effects. These are relevant to a broad number of fields motivated by *individual, organizational, and/or “markets” attitudes toward risk*, as well as by *psychological needs and the need to deal with fundamental economic problems*, which implies taking or accepting some risks [1]. As can be intuitively perceived, risk attitudes are an essential part of our life and their quantitative measurement and pricing is closely linked to the individual and collective rationality households or firms may exhibit when facing risky situations [2–4].

Risk Attitudes: Concepts and EU Theory

Theories based on the valuation of decisions made under uncertainty, both expected and non-expected utility (EU) theories (rank-dependent utility (RDU) theory, regret theory, etc.), have been devised, highlighting and contrasting attitudes toward risks. We turn now to the precise expressions that risk attitudes may take as a function of the “utility” (or “global

goal”) function (*see Utility Function*) under EU rationality. In this section we shall see that there are different approaches and definitions of what may be called *risk attitude* and how it is quantified and measured. The section titled “Generalized Risk Aversion: The Rank-dependent Model” examines risk attitudes within a larger rationality framework. In the section titled “Risk Attitudes and Financial Markets”, we also provide an approach, finance based, which has embedded risk attitudes in assets pricing as well, thereby allowing the exchange of risks between persons, investors, and traders of different risk attitudes.

Expected Utility and the Arrow–Pratt Analysis

The EU is the standard way that economists use to evaluate a random prospect or discrete “lottery” L described by the vector $(x_1, p_1; x_2, p_2; \dots; x_n, p_n)$, whereby it is meant that the consequence x_1 is obtained with probability p_1 , etc. Such a discrete lottery will designate hereunder any institutional kind of risk (investment, industrial performance, etc.). From the point of view of an individual endowed with a utility function $u(\cdot)$ and under EU (*see Utility Function; Subjective Expected Utility*), the lottery is worth $\sum_1^n p_i u(x_i)$. The seminal works by Pratt [5] on the one hand and Arrow [6, 7] on the other hand have shown that one version of the attitude toward risk can be recovered from the explicit specification of the utility function.

Assume an individual endowed with a constant (nonrisky) asset C as well as with an actuarially favorable lottery $\tilde{x}$, i.e., with an actuarial value of $E(\tilde{x}) > 0$ (*see Insurance Applications of Life Tables; Insurance Pricing/Nonlife; Insurability Conditions*). Arrow and Pratt characterized the risk attitude of an individual in relation to the amount, priced p_a , at which an individual would be willing to *sell* the lottery or, in other words, the smallest *nonrandom amount* he would be willing to *receive* to remove the risk faced (an amount often loosely called the *cash equivalent* of the lottery to the given individual). Using the EU rule

$$u(C + p_a) = E[u(C + \tilde{x})] \quad (1)$$

with

$$p_a = E(\tilde{x}) - \pi(C, \tilde{x}) \quad (2)$$

From equation (2), we note that, if the individual wants to be insured against the risk (in case of an

actuarially unfavorable risk), he (she) will accept to *pay* the insurance premium by Arrow–Pratt’s definition. In this case, the individual will be said to display risk aversion. Note that to be accepted, the insurance premium will be *at most*

$$p_I(C, \tilde{x}) = -p_a = \pi(C, \tilde{x}) - E(\tilde{x}) \quad (3)$$

Finding a convenient analytical expression of $\pi(C, \tilde{x})$ seems thus an essential question to solve. Unfortunately, this is a very complicated function for discretionarily large values of $\tilde{x}$. However, Pratt showed that if $\tilde{x}$ displays finite variance and if its range is not too large with respect to C , then π can be satisfactorily approximated by the following expression:

$$\begin{aligned} \pi &\cong \frac{-u''[C + E(\tilde{x})]}{u'[C + E(\tilde{x})]} \cdot \frac{\sigma^2(\tilde{x})}{2} \\ &= \frac{-u''(W)}{u'(W)} \cdot \frac{\sigma^2(\tilde{x})}{2} = A(W) \cdot \frac{\sigma^2(\tilde{x})}{2} \end{aligned} \quad (4)$$

where

$$\begin{aligned} W &= C + E(\tilde{x}), \\ A(W) &= -\frac{u''(W)}{u'(W)} = \frac{d}{dW} \log u'(W) \end{aligned}$$

W is the expected wealth, which reduces obviously to C when $\tilde{x}$ is actuarially fair (i.e., has zero mean). From equation (4), it can be immediately seen that any individual endowed with a concave utility function will have positive $A(W)$ and π , as $u'(W) > 0$ for all possible values of W (by definition of a utility function; see **Subjective Expected Utility**) and as variances are always positive, the sign of π is opposite to that of $u''(W)$, i.e., π will be positive if and only if $u''(W) < 0$, which characterizes a concave utility function. We see below that there exists a simple link between the complicated function in equation (3) and the local approximation in equation (4).

The function $A(W)$ is known as the *Arrow–Pratt coefficient of absolute risk aversion* (hereunder *ARA*), and as equations (2) and (4) show, the larger the function $A(W)$, the smaller the *cash equivalent* (or *selling price*) of any given lottery $\tilde{x}$. By definition, therefore, an individual will be said to be *locally risk averse* if and only if he (she) displays positive π (and hence positive $A(W)$), *locally risk prone* (or risk lover) if she (he) displays negative π (and hence negative $A(W)$), and locally risk neutral if he

(she) displays null π (and hence null $A(W)$). This corresponds respectively to a concave, convex, and affine (or linear) utility function.

Risk can also appear as a multiplicative factor, for example, when an amount a of the assets is invested with risky actuarially favorable return $\tilde{g}$, the rest being held as cash C . Expected wealth is then equal to $W = E(C + a \cdot \tilde{g})$. Maximizing EU then leads to a *relative* risk premium $\pi^* \approx A^*(W) \cdot \sigma^2(g)/2$ by a similar computation. The appropriate coefficient of *relative* local risk aversion (RRA) is dimensionless (a percentage ratio), which is denoted here by $A^*(W)$ with

$$A^*(W) = W \cdot \frac{-u''(W)}{u'(W)} = W \cdot A(W) \quad (5)$$

Yet, these are only *local* properties. In what sense do they transfer to the *finite* case, as described by equations (2–4)? The major contribution of John Pratt has been to show precisely that these local properties convey their message to *the large*. In particular, he showed [5] that three propositions were equivalent when comparing two individuals A and B, or the same individual facing two different situations in terms of wealth:

$$1. \quad \forall W, A_1(W) \geq A_2(W) \quad (6)$$

(The ARA coefficient of individual 1 is never smaller than that of individual 2)

$$2. \quad \begin{aligned} &\exists G : \Re \mapsto \Re, s.t. \\ &G' \geq 0, G'' \leq 0, u_1 = G(u_2) \end{aligned} \quad (7)$$

(The utility function of individual 1 is a concave transform of that of 2) and finally

$$3. \quad \forall C, \tilde{x}, \pi_1 \geq \pi_2 \quad (8)$$

(For all possible wealth, the risk premium of 1 is no smaller than that of 2).

The equivalence of propositions 1 and 3 answers the question raised above, establishing some link between equations (1–3) and equation (4) above. Proposition 2 conveys the meaning of a risk attitude to the concave or convex shape of the Neumannian utility function.

How does the local ARA function $A(W)$ evolve in terms of the (final expected) wealth W of some given individual? If $A'(W) > 0$, ARA increases with wealth and the utility function is said to be endowed with IARA (increasing absolute risk aversion). An

example is provided by any quadratic utility function, say $u(W) = W - bW^2$, with $b > 0$ and $W < \frac{1}{2b}$ (to maintain $u'(W) > 0$, as should be the case for any utility function). If $A'(W) < 0$, ARA decreases with W and the utility function is said to be endowed with DARA (decreasing absolute risk aversion). For example, this is shown by any logarithmic utility function, $u(W) = \ln(W)$. For the special case of CARA (constant absolute risk aversion) utility functions, the exponential utility function $u(W) = -e^{-gW}$ (with $g > 0$) serves an example. In this latter case, $A'(W) = 0$, but it is easy to show that $A^{*'}(W) = g > 0$: we say that this utility function is endowed with increasing *relative* risk aversion (IRRA). Definitions of DRRA (Decreasing Relative Risk Aversion) and CRRA (Constant Relative risk Aversion) functions are then straightforward. The reader will check that the logarithmic utility function provides an example of CRRA, while an example for DRRA functions is given by the power function $u(W) = W^k$, where $0 < k < 1$.

Empirical estimates conducted on stock exchange data as in [8] or [9] indicate that $A'(W) < 0$ and most generally $R'(W) \leq 0$. Experimental studies as in [10] confirm these findings. This demonstrates that quadratic utility functions have been used for convenience in textbooks, but hardly fit observable behavior.

Example and Standard Applications

Consider the following situation: an individual owns $C = \$100\,000$ in a nonrisky asset (e.g., 3-month treasury bonds, or monetary open-end funds' shares), as well as a risky asset $\tilde{x}$ yielding $x_1 = \$22\,500$ with probability 0.7 and $x_2 = -\$10\,000$ with probability 0.3. The utility function is assumed to be $u(W) = W^{1/2}$ or $u(W) = \sqrt{W}$.

Computation of the Risk Premium “in the Large”. The EU of the individual amounts to

$$0.7 \cdot u(122\,500) + 0.3 \cdot u(90\,000) = 335$$

Using equation (1), $E[u(C + \tilde{x})] = 335 = u(C + p_a)$; hence $C + p_a = u^{-1}(335) = (335)^2 = 112\,225$ and thus $p_a = 12\,225$. It is straightforward to compute the *actuarial value* (or expected value) of the risky asset: $\$(22\,500 \times 0.7 - 10\,000 \times 0.3) = \$12\,750$. Equation (2) yields finally $\pi = E(\tilde{x}) - p_a = 12\,750 - 12\,225 = 525$.

Approximate Computation of the Risk Premium “in the Small”. What is the risk premium using the local approximation formula of equation (4)? First, note that from the actuarial value of the risky asset, i.e., $\$12\,750$, the *expected wealth* W is $\$112\,750$. The variance is $\sigma^2(\tilde{x}) = 2\,218\,125 \cdot 10^6$. Thus, from the utility function

$$\begin{aligned} u'(W) &= \frac{1}{2W^{1/2}}, \quad u''(W) = -\frac{1}{4(W)^{3/2}}, \\ r(W) &= \frac{1}{4(W)^{3/2}} \cdot \frac{2W^{1/2}}{1} = \frac{1}{2W} \end{aligned} \quad (9)$$

and from equation (4)

$$\begin{aligned} \pi &\approx r(W) \cdot \frac{\sigma^2(W)}{2} = \frac{1}{2W} \cdot \frac{\sigma^2}{2} \\ &= \frac{1}{225\,500} \cdot \frac{221\,812\,500}{2} = 491.82 \end{aligned}$$

which is the risk premium “in the small”. The relative error committed in using the Arrow–Pratt approximation formula, in this example, amounts to $\frac{525-492}{525} \approx 0.063$, i.e., approximately 6.3% of the risk premium, a relatively small error, though not negligible. However, the reader should convince himself (herself) that the less concave the utility function, the better the approximation in equation (4) and the smaller the error rate on the risk premium (for $u(W) = (W)^{3/4}$, for example, the error rate reduces to 5.3%).

Application: The Standard Simple Portfolio Problem and its Many Interpretations. We have assumed in equations (1) and (2) that the individual owned a given lottery $\tilde{x}$ in addition to his certain amount of cash C_0 , or, more appropriately, in addition to his riskless asset. However, we may often be interested in determining what amount $(1 - a^*)C$ of a (nonrandom) wealth C should be held in the riskless asset and what amount, a^* , should be invested in a single investment yielding a random return $\tilde{\rho}$ (we assume here $\tilde{\rho} > -1$ i.e., no realization of $\tilde{\rho}$ can ever be less than 100%). This standard simple portfolio problem can also be interpreted differently: suppose the agent has to decide what proportion a^* of a risky asset to bear by himself and what part $(1 - a^*)$ to sell to an insurance company for a price defined proportionate to expected compensations for the company. This is a simple insurance portfolio

interpretation found in almost every insurance and economics textbook.

Yet another interpretation can be found in agricultural economics: farmers have to decide ahead of time how much to produce, anticipating (using some probability distribution) the price at which they will be able to sell their produce. If their production function is linear in terms of their joined inputs (equipment, land, and work), $\tilde{\rho}$ can be seen as their unitary profit rate and a^* as the proportion of the production capacity they activate. This somewhat generic problem can be (as a first approximation) formalized as follows:

$$\begin{aligned} \text{Max!} & Eu[(1 - a^*)C(1 + i) + a^*C(1 + \rho)] \\ &= Eu[C(1 + i) + a^*C(\rho - i)] \\ &= Eu(C + a^*C\tilde{x}) \end{aligned} \quad (10)$$

(subject to the constraint $0 < a^* < 1$ iff short sales on markets are forbidden or impossible, and with $\tilde{x} = \tilde{\rho} - i$). Second-order conditions are met as $V(C, a^*) = Eu(C + a^*C\tilde{x})$ is a concave function of the decision variable a^* under risk aversion. The solution a° is then found by equating the first-order derivative to zero:

$$V'(a^\circ) = E[\tilde{x} \cdot u'(C + a^\circ C\tilde{x})] = 0 \quad (11)$$

which determines the proportion to be invested in the risky asset.

Intuitively, if $E(\tilde{x}) = 0$, the proportion a^* will be null (why take the burden of risk, if it does not provide a greater return than the riskless asset?). However, the most interesting property of the solution is that the higher the $A^*(W)$, the lower the $a^*(W)$, which follows the intuition, while a change in the distribution of $\tilde{x}$ has no obvious effect on the demand for the risky asset, as argued by Rothschild and Stiglitz [11]. Some conditions on risk attitude have been determined [12] under which the reduction would necessarily happen, but these conditions are somehow contrived ones in terms of absolute and relative risk attitudes and bear little relevance to empirical observations (which are most likely to require considering not only exogenous but also endogenous risks borne by farmers).

Strong and Weak Risk Aversion: Definition, Relationship

For the reasons just recalled, Rothschild and Stiglitz sought to determine some valid rule based on the

comparative static analysis of risk distributions, instead of remaining in the confines of utility or individual welfare. They were concerned with the issue of defining what “more” risk means [13], without referring exclusively to individual preferences. Denote by F and F^* respectively, the two cumulative probability distributions *with identical actuarial value* defined on some interval, assumed here for simplicity’s sake, to be $[0, M]$, i.e., with

$$\int_0^M F(x) dx = \int_0^M F^*(x) dx \quad (12)$$

They showed that F^* could be defined as *more risky* than F according to three apparently different concepts of “risk increase”, which turn out to be indeed equivalent:

- (a) Any “increase” in risk is what risk averters in the Arrow–Pratt sense hate. This translates to

$$\int_0^M u(x) dF^*(x) dx \leq \int_0^M u(x) dF(x) dx \quad (13)$$

for all individuals endowed with a *concave utility function*. This demonstrates that the two other concepts are equivalent *for distributions having identical mean* to the Arrow–Pratt concept.

- (b) An increase in risk obtains each time we add a “white noise”, i.e., a random variable $\tilde{e}$ with $E(\tilde{e}/x) \equiv 0$, for all x , to some distribution, an operation which does not change the mean. For the two cumulative distributions F and F^* , this is expressed by

$$F^*(\tilde{x}) = F(\tilde{x}) + \tilde{e} \quad (14)$$

This definition follows the common intuition that “when, for each scenario, instead of having one given consequence, we have a distribution around that same consequence, we will face more risk”.

- (c) An increase in risk is characterized by a mean-preserving spread (MPS hereunder). An MPS is defined as some *operator* that takes some probability mass from the center of a given distribution and puts it in the tails of it *without altering the expected value* of the distribution. This translates into

$$F^*(\tilde{x}) = \text{MPS}[\text{MPS}[\dots[\text{MPS}(F(\tilde{x}))]]] \quad (15)$$

i.e., the (more risky) distribution $F^*(\tilde{x})$ is the result of a *finite* sequence of MPS applied to $F(\tilde{x})$. It can be shown [13] that, if the three partial orders that obtain from the three definitions (a), (b) and (c) above, denoted here by $\leq_a$, $\leq_b$, and $\leq_c$, respectively, are mutually compared and compared with the partial order derived from the mean–variance (MV) criterion (denoted here by $\leq_v$), the results can be written as

$$\leq_a \iff \leq_b \iff \leq_c \iff \leq_v \quad (16)$$

In other words, any one of the definitions (a), (b), and (c) of what an “increase” in risk means, matches precisely the other two and is implied by anyone of these two other definitions. This however does not hold for the MV definition, which presumes “too much” with respect to the three other definitions as to what an increase in risk represents.

On the basis of the comparative static analyses of the probability distributions for individual attitudes, a new typology of risk attitude “in the strong sense” can then be generated from Rothschild and Stiglitz’s MPS definition. *Risk aversion* implies that MPS are disliked by the individual; *Risk neutrality* implies that any MPS or finite sequence of MPS in any distribution does not change an individual’s satisfaction; *Risk proneness* finally implies that the individual likes any MPS or finite sequence of it. These definitions are called *in the strong sense* because they imply the Arrow–Pratt definition of risk aversion, but not conversely. The proof is straightforward and left to the reader.

Multiple Dimensions – Background Risk

The analysis presented above relates to any single dimensional risk. A natural question to ask is whether it can be maintained in a multiple dimensional case (for example, defined over many commodities). The answer is negative in general, but three different aspects have to be examined:

1. Can any single index of risk aversion still be meaningful and retain the equivalence of Pratt’s three propositions under multiple dimensional risk?
2. Does the existence of an uninsurable risk (“background risk”) make the individual more or less averse to some given endogenous risk?

3. What about the special case of multiperiod risk and of shifting income from one period to the other?

We take up these three issues successively here.

Index of Risk Aversion under Multiple Dimensions. This first question was originally raised by Kihlstrom and Mirman. Their basic finding was that preference *orderings* defined on commodities play a role in comparing risk attitudes indexes, the latter being linked only to *cardinal* (more accurately *von Neumann–Morgenstern*) *one-dimensional* utility [14]. For example, comparing the risk attitudes of the same individual at different levels of wealth requires that the underlying preferences meet some prerequisite for comparability. For similar reasons, risk attitudes can be compared using the Arrow–Pratt coefficient *only* on the subsets of individuals having the same *ordinal* utility. For example, consider two individuals represented by utility functions u_1 and u_2 respectively, both functions defined on the space of commodities x_1 and x_2 , and two commodities bundles $x^1 = (x_1^1, x_2^1)$ and $x^2 = (x_1^2, x_2^2)$, such that $u_1(x^1) > u_1(x^2)$ and, from the point of view of the second individual, $u_2(x^1) < u_2(x^2)$. Now, consider the lottery $[x^1, p; x^2, (1 - p)]$, with any nonzero value of the probability p , and the sure outcome x^1 . Individual 1 prefers the sure outcome, that individual 2 prefers the lottery. But there would be no meaning in saying that individual 1 is more risk averse than individual 2, for it would be easy to find another lottery and another sure outcome for which the difference in observable choices of the two individuals would be exactly the opposite. The choices suggested here reflect differences between preference orderings rather than differences in risk attitudes.

Karni [15] argued that multivariate risks do not typically pertain to bundle of goods, but rather to the level of income, the uncertainty regarding the ultimate consumption bundle being only an indirect implication. Therefore, the indirect utility function should be the appropriate tool to quantify and measure risk aversion in those cases. One then obtains a *matrix* of local risk aversion indexes, *each* local risk premium being defined in terms of the minimal income necessary to reach the utility level of the commodity bundle (the “expenditure function” of microeconomic theory) at mean prices. This is a simple way of defining the *direction* in which

this balance is to be evaluated in the commodity space: quantifying the risk premium requires indeed specifying this direction.

For interpersonal comparisons on *local* risk aversions, the restriction on *ordinal* preferences does apply, as already mentioned, as well as some additional constraints. The major result in [15], however, is that if these restrictions hold everywhere in the commodity space, it makes sense to determine a *global* interpersonal comparison of risk attitude *independent of differences in ordinal preferences*, a unique result in the literature on multivariate risk. Other developments always rely on similar ordinal preferences [16].

Background Risk. As early as 1981 [17], it was discovered that the Arrow–Pratt definition was not “strong” enough in another sense: in the presence of another risk that the individual could not get rid of (“background” or “uninsurable” risk), an increase in risk aversion does not imply that the demand for any other independently distributed risky asset will decrease. In other words, $a^*(W, x)$ is not necessarily inversely related to $A^*(W)$ in the presence of background risk. For example, not taking into account the risk on human capital when estimating the optimal portfolio of assets can lead to overestimation of the demand for – and hence the price of – the risky asset. Following the equivalence recalled above from Rothschild and Stiglitz’s work, adding a white noise to some undesirable lottery might make that lottery desirable, if some background risk exists, which is quite a paradoxical result.

To avoid such results, Ross suggested a “strong” risk aversion concept [17] calling, in the interpersonal comparison problem, for:

$$\inf \frac{u_1''(w)}{u_2''(w)} \geq \sup \frac{u_1'(w)}{u_2'(w)} \quad (17)$$

or, equivalently:

$$\exists \lambda \in \mathbb{R}, \forall (w_1, w_2) s.t. \frac{u_1''(w_1)}{u_2''(w_1)} \geq \lambda \geq \frac{u_1'(w_2)}{u_2'(w_2)} \quad (18)$$

He showed [17] that this definition implies Arrow and Pratt’s definition immediate result, but not conversely (take some exponential utility function and give a counterexample). This result has been acknowledged

to attempt an explanation of the equity premium (expected net excess return $E(\tilde{r})$ of holding the market portfolio of risky assets over the risk-free rate of interest r_f), mostly “underpredicted” by standard EU models. Indeed, if one uses the values of the Arrow–Pratt RRA index recovered from empirical investigations, which mostly fall on or around the interval [2, 4], one can find the equity premium as being within the interval [.10, .20]. In contrast to that figure, known empirical observations [18] display an interval of [5, 7]. The equity premium would thus be undervalued by simple traditional EU reasoning by about 40 times! But it has been argued [19] that, if labor income risk is neither insurable nor diversifiable, this “background noise of life” [17] might explain, if not all, at least part of that puzzling gap between direct observations of the equity premium and computations from observations of RRA.

Yet, Ross had called for a research program consisting in defining a canonical class of utility functions, which would parametrically fit the requirement that Arrow–Pratt risk averse individuals would be made more risk averse when adding some background risk. This program has been fulfilled in the late 1980s and 1990s by Pratt and Zeckhauser, who defined *proper risk aversion* [20], then by Kimball [21], who defined *standard risk aversion*, and finally by Gollier and Pratt [22], who defined *risk vulnerability*. The latter concept is a generalization of the two preceding ones. It implies that the two first derivatives of the utility function are concave transforms of the original utility function. Vulnerability is both necessary and sufficient for the introduction of an unfair background risk to lower the optimal investment in any other independent risk, provided the risk to be borne is *independent* of the background risk. This concept of vulnerability has made harmonic absolute risk aversion (HARA) utility functions popular to the extent that they all represent individuals sensitive to locally proper and proper risks (in the sense of Pratt and Zeckhauser [20]), who, *a fortiori*, are risk vulnerable individuals.

Correlated Investment Risk and Background Risk.

This issue calls for a more detailed characterization, which is dealt with by Eeckhoudt *et al.* [23] and Ross [24]. The latter author draws in particular attention to the fact that two separately undesirable risks can be jointly desirable. Looking backward, this reminds

one of the Allais [25] *versus* the *main stream* debate: there can be, indeed, preferential positive synergies between two risks.

Income Timing and Risk. The preceding extensions and qualifications on risk aversion have mostly dealt with empirical issues making the portfolio or risky investment problem less simple than it first appeared to be. But one should not lose sight of the savings problem mentioned above. This problem has a seemingly different flavor than that of the portfolio, to the extent that it has also to deal with a specific intertemporal trade-off question: how does saving change when risk affecting future income rises? In some sense, this old idea of Keynes (the “precautionary motive” for saving) calls for a special multidimensional extension of the risk attitude question, utility being in this question defined on two dimensions, today’s consumption and tomorrow’s income. Trying to recover an expression for risk aversion similar to that of Arrow and Pratt has long been a concern to authors like Drèze and Modigliani [26], Caperaa and Eeckhoudt [27], Machina [28], Bryis *et al.* [29], Menezes and Hanson [30], and finally Kimball [21]. The story is told in part by Munier [31]. It led to the formal definition of prudence given by Kimball [21].

By definition, an agent can be said to be prudent if and only if the marginal utility of future consumption is convex. In such a case, it has been known since the late 1960s that the willingness to save would increase in response to an increase in a noninsurable risk bearing on the future wealth of some individual. Kimball [21] thus raises the question in terms that are quite different from those of Arrow and Pratt: the issue here is not to determine how much of a *compensating* balance should be given to some individual to *get rid* of some risk, but how much of an *equivalent* balance should be given to that individual in order for him to *take the same decisions* as without any (increase in) risk bearing on his future income and thus to *restore his utility* level. Prudence – or the intensity of the precautionary saving motive – will thus be measured by the *precautionary equivalent premium* ψ^e . Kimball shows that, assuming time separability of utility,

$$\psi^e[C_0, \tilde{x}, u(C_0 + \tilde{x})] = -\frac{u'''(w)}{u''(w)} \cdot \frac{\sigma^2(\tilde{x})}{2},$$

with $w = E(C_0 + \tilde{x})$ (19)

where the coefficient of prudence appears as

$$A_P = \frac{-u'''(w)}{u''(w)} \quad (20)$$

The empirical studies that have been conducted show that people more exposed to future income risk save more. *Prudence* is therefore a widely accepted concept. Moreover, prudence is a necessary condition for DARA, which is also a widely accepted view.

Relation between Mean–Variance and other Risk Models

Prior to Rothschild and Stiglitz [11], pointing out that the MV analysis was not entirely consistent with EU analysis, Borch’s counterexample [32] had been received as a blow to it, particularly in the financial community [33]. Given any two probability distributions, assume some individual sees them as equivalent in view of their respective means and variances. Borch then shows that one can construct, using only the means and variances of these two initial distributions, a new distribution with the same mean and the same variance as the earlier two, but which is nevertheless first order stochastically dominating (or FSD), one of the two initial distributions, providing thereby a clear contradiction to MV analysis. In general, indeed, one needs many more than two moments to entirely characterize a distribution. In addition, any convex combination of two assets with distributions of returns characterized by the same two moments would not necessarily yield the same type of distribution. For a while, standard portfolio theory seemed to be bogged down! Empirical research showed however that, at least over some period of time, differences in portfolios performances – under MV *versus* EU – would not be large, and the financial community continued using standard MV analysis at least as an approximation tool (see also [34–37]).

Meanwhile, the question as to whether there were some conditions under which EU and MV analysis could be considered as analogous or at least close to each other had been seriously raised. Meyer [38] provided a case paper in this direction.

A quantitative treatment of measures of risk attitudes and their correspondence between MV and EUs approaches can be found in Eichner and Wagener [39], building on results by Owen and Rabinovitch [40] and Meyer [38] showing that, if all distributions $\tilde{W} \in \Omega$ differ only by location along their real

line support and by scale, any of them is equal in distribution to $\mu_W + \sigma_W X$ if X is the normalized random variable of any element of Ω . Any *expected utility* defined on that class of distributions can then be written as a function of the couple (μ_W, σ_W) . We denote such EU by $U(\mu_W, \sigma_W)$. Denoting the wealth state of the investor by W , and the k th derivative with respect to wealth by $u^k(W)$, the ratio

$$\forall W \in \mathfrak{R}, A_n(W) = -\frac{u^{n+1}(W)}{u^n(W)} \quad (21)$$

obviously yields the Arrow–Pratt particular measurement of ARA for A_1 , while A_2 and A_3 are used to denote quantitative estimates of absolute *prudence* (see the section titled “Correlated Investment Risk and Background Risk”) and absolute *temperance* respectively. The case of $n = 4$ yields a ratio, which plays a role in Caballe and Pomansky’s concept of “mixed risk aversion” [41].

A number of relationships of that sort allow extending, for the given class Ω of random variables, some of the results recalled here above to MV analysis. Meyer [38] claimed that the class Ω of random variables covers a wide range of economic problems.

Generalized Risk Aversion: The Rank-dependent Model

From the late 1970s onward, one of the alternative models to EU has gained popularity and has been studied and used extensively: the RDU model. Essentially, RDU claims, on experimental [25, 42] and empirical grounds, that probabilities in the vector p are, under risky conditions, being *transformed* into a vector $h(p)$ (in which each element is denoted by $h_i(p)$) while being applied in evaluating risk, or, under uncertainty, that *decision weights* $h_i(p)$ [43] or nonadditive probabilities [44] are being used. Note that the model’s basic feature is that one should take into account the *whole* distribution – the vector p – should be taken into account to evaluate a prospect, expressing thus risk attitude as a result of the *whole* distribution, an old idea first expressed by Allais.

Under such a scheme, risk attitude is generalized and consists of two parts:

1. Probabilistic attitude toward risk, represented by the impact of the transformation function

$\theta(p)$ under risky conditions [43, 45]. The transformation function is usually defined on the decumulative distribution. It then yields decision weights

$$h_i(p) = \theta\left(\sum_{j=i}^n p_j\right) - \theta\left(\sum_{j=i+1}^n p_j\right) \quad (22)$$

where i is the index of the *ranked* (in increasing order) outcomes. Hence RDU (Rank Dependent Utility model).

2. Transformed Arrow–Pratt risk attitude, as illustrated by decreasing marginal utility and described above, *but computed using transformed probabilities*.

Hilton [46] was then able to decompose the individual overall risk premium in such an environment into two parts, given a prospect $L = (x_1, p_1, \dots, x_n, p_n)$ and transformed weights $h_i(p)$ of the probabilities p_i , as follows:

- *Transformed Arrow–Pratt risk premium* $\pi_h(L)$ (note that decision weights are used in the formula):

$$u\left[\sum_{i=1}^{i=n} [h_i(p)x_i - \pi_h(L)]\right] = \sum_{i=1}^{i=n} h_i(p)u(x_i) \quad (23)$$

- *Decision weights risk premium* π_w , representing “probabilistic” risk attitude:

$$\pi_w(L) = \sum_{i=1}^{i=n} p_i x_i - \sum_{i=1}^{i=n} h_i(p) x_i \quad (24)$$

- *Overall transformed risk premium* $\pi^0(L)$

$$u\left[\sum_{i=1}^{i=n} p_i x_i - \pi^0\right] = \sum_{i=1}^{i=n} h_i(p)u(x_i) \quad (25)$$

It is straightforward to show that $\pi^0(L) = \pi_h(L) + \pi_w(L)$. The most common interpretation consists in viewing $u(\cdot)$ as a *von Neumann–Morgenstern* utility function, in which case there is a real split between two different parts of risk attitude. Allais [25, 47] and others interpret $u(x)$ as a Bernoullian utility function whose shape is *explained* by the evaluation of marginal wealth but has *straightforward implications* by Jensen’s inequality for choosing prospects under risk, in which case the “probabilistic”

part is the *only* measure of attitude toward risk properly defined (for related issues, see [48, 49]). In any case, the generalization achieved by RDU theory with respect to EU theory is that risk aversion can emerge without implying any concavity of the utility function.

Risk Attitudes and Financial Markets

Recently, a broad number of techniques, statistical and otherwise, are applied to estimate and reveal the implied risk attitudes of decision makers. Some of these techniques include models we construct to reflect risk attitudes (embedded in explicit utility functions or derived by models that presume a broad range of potential risk attitudes as seen above), tested and confronted with statistical evidence. In other cases, attitudes are determined through the implied preferences in the utility function of a person, an investor, trader, or risk manager. In finance, risk attitudes or persons combine through an exchange between agents with different risk attitudes to determine the price of risk (implied in a “risk neutral distribution” (RND), based on the presumption that markets are “always” reflecting a rational behavior and a risk attitude, which we seek to reveal through the measurement of asset prices). In this sense, the finance, money-based, approach to risk attitudes is similar to the above developments. These models are of course just models, in the sense that they are limited, reflecting the model builder’s understanding of behavioral and economic attitudes, limitations, and bounded rationality, and thereby attitudes to specific events.

Finance uses instruments such as options, contracts, swaps, insurance, investment portfolios, etc. so that risks can be exchanged among traders and investors with broadly varying risk attitudes. When risks are priced by financial markets, they can be traded and distributed in a manner that benefits “all”, i.e., in a manner that those investors with different attitudes and willing to assume more risks will do so and those who seek to assume less risk will do so as well. Of course, this is possible if an exchange between such investors and traders can be realized. The market price is then the mechanism that allows such an exchange and reflects traders’ attitude to risk. When this is not the case, and risks are valued individually, implicitly due to individuals’ attitudes

to risk, a broad number of approaches are used to mitigate their effects. As noted above, measures of risk attitudes commonly used and based on EU are based on utility functions. Recently, attempts have been made to empirically characterize the risk aversion by extracting the RND, expressing the market (consisting of a large number of investors, speculators, buyers, and sellers) attitude toward future potential events and their probabilities. In this sense, market data can provide an implied risk aversion that the market is presumed to have. Investors are not indifferent to risk and their corresponding subjective probability is thus different than the RND. In fact, the RND is adjusted upward (or downward) for all states in which the dollars are more (or less) highly valued. Hence the higher the risk aversion, the more different the RND and the subjective probability. The risk aversion can thus be estimated from the joint observation of the two densities (see [50–54]). In other words, the index of ARA $A(\cdot)$, can be written as a functional relationship (assuming away the generalization of the section titled “Generalized Risk Aversion: The Rank-dependent Model”):

$$A(\cdot) = f(\text{RND, subjective probability}) \quad (26)$$

This was exploited by Jackwerth [51] and Ait-Sahalia and Lo [53] while extracting a measure of risk aversion in a standard dynamic exchange economy as in [55]. Such a relation can be defined simply by maximizing the EU of a portfolio at a future date whose current price is \$1 and using the investor’s subjective probability distribution in valuing the utility of money. In this formulation, risk attitude is a function of the risk neutral and the investor’s subjective probability distributions. Given any two of these elements, the third can then be inferred. This has led to empirical applications where the implied risk attitude can be determined on the basis of market option prices (where the implied RND can be determined using option prices for example). This important observation can be determined simply as we shall see below.

Assume that markets are complete. Then, a portfolio price is necessarily equal to the discounted future portfolio price with expectation taken with respect to the RND and discounted at the risk-free rate. A simple mathematical formulation that simultaneously captures an investor’s risk attitude, his subjective probability, and the market RND consists in maximizing the investor future EU subject to the current

market pricing of the portfolio (using a RND). Letting, for convenience, the current market price of the portfolio be \$1, we have the following problem:

$$\begin{aligned} & \text{Max}_W E_S u(W_T) \\ & \text{Subject to : } 1 = \frac{1}{(1+r_f)^T} E_{RN}(W_T) \end{aligned} \quad (27)$$

where W_T is the terminal time T portfolio price whose utility we seek to maximize and r_f is the risk-free market rate. Let λ be the constraint Lagrange multiplier. Then, optimization leads to the first-order condition:

$$u'(W_T) = \frac{\lambda}{(1+r_f)^T} \frac{f_{RN}}{f_S} \quad (28)$$

where $f_S(\cdot)$ and $f_{RN}(\cdot)$ are the subjective and the risk neutral distributions. An additional derivative with respect to the portfolio price W_T at time T yields after some elementary manipulations an index of ARA, which is given by the derivative with respect to wealth of a function for “discriminating” between the subjective and the risk neutral distribution:

$$A(W_T) = \frac{d}{dW_T} g(W_T), \quad g(W_T) = \ln \frac{f_S(W_T)}{f_{RN}(W_T)} \quad (29)$$

A broad number of techniques can then be used to estimate empirically the RND (for example, by using market data on derivatives and calculating the implied RND). This establishes a specific relationship between risk attitude and the subjective probability distribution.

For example, if the utility of an investor is assumed to be HARA (hyperbolic absolute risk aversion) with an index of ARA, $A(W_T)$, given by

$$\begin{aligned} u(W_T) &= \frac{1-\gamma}{\gamma} \left\{ \frac{aW_T}{1-\gamma} + b \right\}^\gamma, \\ A(W_T) &= \frac{a}{\left\{ \frac{aW_T}{1-\gamma} + b \right\}} \end{aligned} \quad (30)$$

Then, additional elementary manipulations indicate that

$$\begin{aligned} A(W_T) &= \frac{a(1-\gamma)}{aW_T + b(1-\gamma)} = \frac{d}{dW_T} g(W_T) \\ \text{and } (aW_T + b(1-\gamma))^{(1-\gamma)} &= \frac{f_S(W_T)}{f_{RN}(W_T)} \end{aligned} \quad (31)$$

Similarly, assume that both the subjective and the risk neutral distributions are normally distributed with means and variances given by (μ_S, σ_S^2) and $(\mu_{RN}, \sigma_{RN}^2)$. Then,

$$\begin{aligned} \frac{f_S(W_T)}{f_{RN}(W_T)} &= \frac{\sigma_{RN}}{\sigma_S} \\ &\times \exp \left[-\frac{(W_T - \mu_S)^2}{2\sigma_S^2} + \frac{(W_T - \mu_{RN})^2}{2\sigma_{RN}^2} \right] \end{aligned} \quad (32)$$

Therefore,

$$\begin{aligned} A(W_T) &= \frac{d}{dW_T} \left(\frac{\ln(\sigma_{RN} - \sigma_S) - \frac{(W_T - \mu_S)^2}{2\sigma_S^2} + \frac{(W_T - \mu_{RN})^2}{2\sigma_{RN}^2}}{\frac{(W_T - \mu_S)^2}{2\sigma_S^2} + \frac{(W_T - \mu_{RN})^2}{2\sigma_{RN}^2}} \right) \\ &= W_T \left(\frac{\mu_S}{\sigma_S^2} - \frac{\mu_{RN}}{\sigma_{RN}^2} \right) \end{aligned} \quad (33)$$

Thus, if $\frac{\mu_S}{\sigma_S^2} < \frac{\mu_{RN}}{\sigma_{RN}^2}$, risk aversion decreases linearly in wealth and vice versa. Note that a risk aversion is then defined by the sign of $A(W_T)$ as defined in this artificial example. In this sense, a risk attitude can be revealed by the market. Evidently, for a risk neutral investor, we have $A(W_T) = 0$ and

$$\ln \left(\frac{f_S(W_T)}{f_{RN}(W_T)} \right) = 0, \text{ or } f_S(W_T) = f_{RN}(W_T) \quad (34)$$

Higher-order risk attitudes can be similarly defined. Explicitly, the index of prudence can be defined as well in terms of the subjective and risk neutral distributions logarithmic function $g(W_T)$ and given by

$$A_P = \frac{g''(W_T)}{g'(W_T)} - g'(W_T), \quad g''(W_T) = (A_P + A)A \quad (35)$$

If an investor is risk averse, $A > 0$ and therefore, $g''(W_T) > 0$ (an increasing rate of discrimination rate with respect to wealth) implies prudence since $A_P > 0$. However, if empirical analysis indicates $g''(W_T) < 0$, then the prudence index is both negative and larger than the index of risk aversion. Extensive research, both theoretical and empirical, has extended this approach and indicated a number of important results. For example, risk attitude is not only state varying but is time varying as well. Further, it clearly sets out the concept of risk attitude in terms of a

distance between the subjective and the risk neutral (market) distributions. Again, in the case of the artificial normal example treated earlier, we have an index of prudence given by

$$A_P = \frac{1}{A} \left(\frac{1}{\sigma_{RN}^2} - \frac{1}{\sigma_S^2} \right) - A \quad (36)$$

In this equation, we clearly see the relationship between the risk neutral, the subjective, and the risk attitude of the investor, both with respect to the index of ARA and the investor's prudence.

Risk Characterization

During the past decade, there has been a trend of using stochastic techniques in risk assessment to characterize risk more completely [1–4]. The results of these analyses can be summarized in the form of a distribution of possible risks within the exposed population, taking into account as many sources of uncertainty and variability as possible. This distribution indicates the maximal and minimal risks that might be experienced by different individuals and the relative likelihood of intermediate risks between these two extremes. Finley and Paustenbach [5] discuss the benefits and disadvantages of using probabilistic exposure assessment compared with using point estimates. Point estimates are simple and user-friendly but tend to overestimate exposure and provide no indication of confidence. Generally, risk and exposure are computed as a function of the number of risk factors. These factors may be thought of as input variables for a model in which the output is a quantitative measure of risk or exposure. Often, there is prior information about the admissible ranges or shape of the distributions of the input variables. An integrated environmental health risk assessment model (*see* **Environmental Health Risk**) gives a complete picture of the environmental risk assessment, including source characterization, fate and transport of the substance, exposure media, biological modeling, and estimation of risk using dose–response modeling (*see* **Dose–Response Analysis**). To the extent possible, distributions characterizing the uncertainty associated with each adjustment factor are developed using scientific knowledge. Comprehensive realism allows for characterizing the impact of professional judgments and assumptions on risk estimation by presenting a decision tree for systematically displaying all plausible scenarios [6]. Thus, the information upon which health risk assessment is based is subject to numerous factors called *risk factors*. Whether the assessment relies on data obtained from human epidemiological studies or on surrogate data such as animal bioassays (*see* **Cancer Risk Evaluation from Animal Studies**), the distribution of risk factors affects the reliability of risk estimates and the interpretation of the assessment results.

In the characterization of risk, risk factors can be categorized into two main groups, potency and exposure. Potency can be further classified by risk

factors. When human risks are predicted on the basis of toxicological data, there is a factor related to extrapolating the effects of the high doses used in laboratory studies to those of the lower levels of exposure typically experienced by humans under natural conditions. In addition, risk factors can include translating findings from laboratory animals data to humans, extrapolating toxicological results obtained *via* one route of exposure (oral, inhalation, or dermal) to another route, or using results of subchronic toxicity studies to predict chronic effects [7].

The exposure factor is equally important in characterizing risk. Building a proper distribution of the exposure factor is the key in estimating exposure. Epidemiological data on exposed human populations are subject to variability [8, 9]. Not only is exposure difficult to assess, both retrospectively and prospectively, but disease status could be in error. Retrospective exposure profiles can be difficult to construct, particularly in terms of chronic diseases such as cancer, for which exposure data from many years prior to disease ascertainment are needed. For example, radon measurements in homes taken today may not reflect past exposures because of changes in dwelling address, building renovations, or lifestyle (e.g., sleeping with the bedroom window open or closed), or inherent variability in radon measurements (*see* **Radon**). Exposure in prospective studies may also be quite variable. In dietary studies, for example, both dietary recall and food diaries can be subject to error. In epidemiological studies using computerized systems to link exposure data from one database with health status data in another database, even vital status (whether a subject is living or dead) can be in error [8]. Furthermore, because many epidemiological investigations are based on occupational groups with higher levels of exposure than the general population, uncertainty arises when data from occupational studies (*see* **Occupational Cohort Studies**) are extrapolated to environmental exposure conditions [10]. For example, lung cancer risks experienced by underground miners exposed to high levels of radon gas in the past may be used to predict the potential risks associated with lower levels of radon present in homes today [10].

For the purposes of this article, we will consider risk as a function of input (or risk) factors that are subject to uncertainty and variability. When the input

variable is fixed (deterministic in a broad sense) but unknown, the distribution of values obtained from repeated observations represents uncertainty. The repeated observations can be used to construct a confidence interval for which there is a given percent chance of bounding the true value. Note that large amounts of uncertainty indicate that there may be opportunities to improve the information base for decision making by conducting additional research in areas where information is most doubtful. When the input variable is stochastic and represented by a distribution with known parameters, variability is present in the input variable. Note that, other things being equal, a great deal of real variability indicates that societal resources can be more efficiently targeted to reduce risk where it is the most intense. Some risk factors have both uncertainty and variability, while some have only one. Details about uncertainty and variability and their impact on risk characterization are discussed in another entry of this encyclopedia (see **Uncertainty and Variability Characterization and Measures in Risk Assessment**).

In the remainder of this chapter, we will consider a general framework for risk characterization in a multiplicative model and in a general risk model in which the input variables are stochastic. In the section titled “General Risk Model Incorporating Stochastic Risk Factors”, we examine a general risk model using the example of characterizing the risk of lung cancer due to radon exposure. In the section titled “Multiplicative Risk Model: Ingestion of Contaminated Fish”, we characterize risks in a multiplicative model using the example of risk assessment for individuals who ingested contaminated fish [11]. In the section titled “Multiplicative Risk Model: Ingestion of Contaminated Fish”, we conclude with a discussion about the assumptions.

General Risk Model Incorporating Stochastic Risk Factors

Rai *et al.* [12] have developed a general framework for characterizing and analyzing uncertainty and variability for arbitrary risk models. Suppose that the risk R depends on p risk factors $X_1, \dots, X_p$ according to the function

$$R = H(X_1, X_2, \dots, X_p) \quad (1)$$

Each risk factor X_i may vary within the population of interest according to some distribution with

a probability density function $f_i(X_i|\theta_i)$, which is conditional upon the parameter θ_i , which may or may not be known. When a parameter is unknown, the uncertainty in X_i is characterized by the distribution $g_i(\theta_i|\theta_i^0)$ for θ_i , where θ_i^0 is a known constant. The stochastic risk factor (with total uncertainty/variability) X_i is then described by the density function

$$c_i(X_i|\theta_i^0) = \int f_i(X_i|\theta_i)g_i(\theta_i|\theta_i^0) d\theta_i \quad (2)$$

If θ_i is a valued vector, then g_i is a multivariate distribution. Here, we assume that the forms of the distributions f and g are known. Usually, a risk factor is considered a lognormal distribution, i.e., $f_i(X_i|\theta_i)$ has a lognormal distribution, with either known or unknown parameters. The most common distributions for unknown parameters are triangular distributions. The $g_i(\theta_i|\theta_i^0)$ has a triangular distribution for the mean and standard deviation parameters of $\log X$.

For any correlated pair (i, j) , let X_i and X_j have a joint distribution f_{ij} , conditional upon the parameter θ_{ij} . Here, f_{ij} represents the joint distribution of variability in X_i and X_j . The parameter vector θ_{ij} , in turn, possibly has a multivariate distribution g_{ij} with the known parameter θ_{ij}^0 . Here, g_{ij} represents the joint distribution of uncertainty in X_i and X_j .

Risk Distributions

To characterize risk, we will consider the distribution of $R^* = \log H(X_1, X_2, \dots, X_p)$. Allowing for both uncertainty and variability in risk, the distribution of R^* is given by

$$C^*(R^* \leq r^*) = \int_{\log H(x_1, \dots, x_p) \leq r^*} \int c(X_1, \dots, X_p|\theta^0) \times dX_p \dots dX_1 \quad (3)$$

where $c(\cdot)$ is a joint density function of all the risk factors; the parameter of this joint distribution is $\theta^0 = \{\theta_i^0, \theta_{ij}^0; i, j = 1, \dots, p\}$. The joint density function $c(\cdot|\theta^0)$ can be partitioned into two parts: $f(\cdot|\theta)$ represents the joint density due to variability in the risk factors and $g(\cdot|\theta^0)$ represents the joint density function due to uncertainty in the risk factors. The probability function in equation (3) can be further

expanded as follows:

$$C^*(R^* \leq r^*) = \int_{\log H(x_1, \dots, x_p) \leq r^*} \int \{f(X_1, \dots, X_p | \theta) \times dX_p \dots dX_1\} \{g(\theta | \theta^0) d\theta\} \quad (4)$$

The mean and variance of the distribution of R^* can be approximated by $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and $W(R^*)$.

If all of the risk factors in equation (1) are log-normally distributed and the risk model is of the multiplicative form, then the distribution of R^* is normal with a mean $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and variance $W(R^*)$. Sometimes, risk factors are assumed to be a beta, triangular, or log-triangular distribution, if not lognormally distributed. In that case, they can be approximated very well by a lognormal distribution. Thus, if all of the risk factors are approximately log-normally distributed, the distribution of R^* can be approximated by a normal distribution. The distribution of R^* can also be approximated by Monte Carlo simulation. Although straightforward, Monte Carlo simulation can become computationally intensive with a moderate number of risk factors.

To apply the Monte Carlo method, we simply draw a random sample of the values of the risk factors from the distribution $c(\cdot)$ and calculate the value of R^* based on that sample. Repetition of this procedure for a sufficiently large number of times yields the Monte Carlo distribution of R^* . Note that when $\{X_i\}$ are independent, values of the risk factors can be generated from their marginal distributions $\{c_i\}$.

Multiplicative Risk Model: Ingestion of Contaminated Fish

Consider the example analyzed by Hoffman and Hammonds [11] and reanalyzed by Rai *et al.* [12]. In this example, a multiplicative model is used to estimate the hazard quotient for a group of individuals potentially exposed to risk through the ingestion of contaminated fish. Here, risk is defined by the hazard quotient, which is equal to exposure divided by the reference dose. Exposure to the contaminant is estimated by multiplying the concentration of the contaminant in the fish X_1 by the ingestion rate of fish X_2 and then normalized by dividing by the body mass of a human X_3 and the reference dose X_4 . The

risk R can then be expressed as

$$R = X_1 \times X_2 \times (X_3)^{-1} \times (X_4)^{-1} \quad (5)$$

The risk factor X_4 is assumed to be subject to uncertainty only. For a specific human population of interest (with known mean and standard deviation), X_3 is subject to variability only. However, when extrapolating to a general human population, X_3 is also subject to uncertainty. The remaining variables X_1 and X_2 are assumed to be subject to both variability and uncertainty. (Characterizations of distributions of the risk factors are given in Table 1 of Rai *et al.* [12], and the resulting distributions are depicted in Figures 2 and 3 of the same reference.)

Complex Risk Model: Residential Radon Exposure

In this section, we apply the methods described in the section titled “General Risk Model Incorporating Stochastic Risk Factors” to characterize a general risk model for estimating lung cancer risk due to residential exposure to radon [13, 14]. A number of factors can influence radon risk estimates. The primary concern is the excess risk of lung cancer demonstrated in 11 cohort studies of underground miners conducted in a number of countries around the world. α Particles emitted by radon daughters appear to exert radon’s carcinogenic effects by causing DNA damage to lung tissue. Thus, even low levels of exposure to radon can confer some increase in risk. After considering different possible approaches to risk estimation, the Biological Effects of Ionizing Radiation (BEIR) VI Committee elected to base risk models on epidemiological data derived from studies of the mortality of miners. The committee conducted a combined analysis of updated data from the 11 miner cohorts and developed two models for projecting lung cancer risks in the general population. These two models are referred to as the *exposure-age-concentration* and *exposure-age-duration* models. We will demonstrate using the exposure-age-duration model.

If e_t denotes the excess relative risk (ERR) at age t , then

$$e_t = \beta \times \omega(t) \times \phi(t) \times \gamma_{\text{dur}}(t) \times K \quad (6)$$

The factor β ($(\text{Bq}\cdot\text{m}^3)^{-1}$) reflects the carcinogenic potency of radon, as modified by the other risk factors in model (6). The last term in this model is the dosimetric K factor (dimensionless), which is used to extrapolate from the conditions of occupational exposure to those of environmental exposure. The factor $\omega(t)$ represents a time-weighted average exposure to radon, expressed in $\text{Bq}\cdot\text{m}^3$, within exposure-time windows 5–14, 15–25, and 25+ years prior to disease diagnosis. The factor $\omega(t)$ can be expressed as follows:

$$\begin{aligned}\omega(t) &= \omega \times [\nabla_{[5,14]}(t) + \theta_2 \nabla_{[15,24]}(t) + \theta_3 \nabla_{[25,\infty]}(t)] \\ &= \omega \times \eta_t\end{aligned}\quad (7)$$

where

$$\nabla_{[a,b]}(t) = \begin{cases} 10 & \text{for } t > b \\ (t-a) & \text{for } a \leq t \leq b \\ 0 & \text{otherwise} \end{cases} \quad (8)$$

The factor $\phi(t)(y^{-1})$ indicates the effects of attained age, categorized into four broad age groups:

$$\phi(t) = \begin{cases} \phi_1 & \text{for } t \leq 54 \\ \phi_2 & \text{for } 55 \leq t \leq 64 \\ \phi_3 & \text{for } 65 \leq t \leq 74 \\ \phi_4 & \text{for } t \geq 75 \end{cases} \quad (9)$$

The factor $\gamma_{\text{dur}}(t)(y^{-1})$ reflects the duration of exposure to radon (in years), where

$$\gamma_{\text{dur}}(t) = \begin{cases} \gamma_{d1} & \text{for } t < 10 \\ \gamma_{d2} & \text{for } 10 \leq t < 20 \\ \gamma_{d3} & \text{for } 20 \leq t < 30 \\ \gamma_{d4} & \text{for } 30 \leq t < 40 \\ \gamma_{d5} & \text{for } t \geq 40 \end{cases} \quad (10)$$

Our interest lies in risks associated with low (residential) radon exposures in middle-aged to elderly population. We demonstrate the risk characterization for the exposure-age-duration model for any person older than 40 years, for which $\gamma_{d5} = 10.18$. In this analysis, the risk function (equation (7)) represents the age-specific *ERR* model, which is represented as a product of four factors: the carcinogenic potency of radon $\beta = X_1$, the exposure to radon $\omega\eta_t = X_2$, the effect of age $\phi = X_3$, and $K = X_4$. Thus,

$$ERR = X_1 \times X_2 \times X_3 \times X_4 \times \gamma \quad (11)$$

where $\gamma = 10.18$. For simplicity, we assume that γ is a constant, i.e., it has neither uncertainty nor

variability. Note that the risk factors X_1 , X_2 , and X_3 are correlated. In this application, X_1 and X_3 are assumed to be subject to uncertainty only, and X_2 and X_4 are assumed to be subject to both variability and uncertainty.

The basic distribution assumptions are given in Tables 1a and 1b in [13]. The carcinogenic potency of radon X_1 is assumed not to vary among individuals, reflecting equal individual sensitivities within the average population. Uncertainty in X_1 is characterized by a lognormal distribution, with known geometric mean and geometric standard deviation. The level of radon $\omega = X_2/\eta_t$ is assumed to vary among homes in accordance with a lognormal distribution. Uncertainty in radon levels is described by means of lognormal distributions for both the geometric mean and geometric standard deviation of the distribution of radon levels. Although the modifying effect of age X_3 is assumed not to vary among individuals within a given age group, uncertainty is described by means of a lognormal distribution. Variability in the K factor X_4 is characterized by a log-uniform distribution for the geometric standard deviation. This description of uncertainty and variability was guided by both empirical data and expert judgment on the part of the BEIR VI Committee. The covariance structure used to define the correlation matrix is given in Table 2b in [13]. This correlation structure is based on the covariance matrix obtained when estimating the model parameters. Other than the statistical correlation between X_1 and X_3 , which is induced by the estimation procedure, the risk factors are assumed to be independent. Using these interlinked distributions, the distribution of risk can be estimated for different sections of the population.

Characterization of Lifetime Relative Risk of Lung Cancer due to Radon Exposure

To determine the lifetime relative risk (LRR) of radon-induced lung cancer, we require the hazard function (see **Hazard and Hazard Ratio**) for the death rate in the general population. Deaths can be classified into two categories: those due to lung cancer and those due to other competing causes. Assume that the age at death, T , is a continuous random variable. Let $h(t)$ be the rate of lung cancer

deaths and $h^*(t)$ be the rate of overall deaths at age $T = t$, in an unexposed population. Furthermore, let $e(t)$ be the ERR in an exposed population. The death rate due to lung cancer in the exposed population at age t is $h(t) + h(t)e(t)$, and the overall death rate is $h^*(t) + h(t)e(t)$.

Let $R(t)$ be the probability of death due to lung cancer for a person of age t , and $S(t)$ be the survival probability up to age t in the exposed population. Following Kalbfleisch and Prentice [15], the survival function can be expressed as

$$S(t) = \Pr\{T \geq t\} \\ = \exp \left\{ - \int_0^t [h^*(u) + h(u)e(u)] du \right\} \quad (12)$$

and the probability of death due to lung cancer, $R(t)$, can be written as

$$R(t) = [h(t) + h(t)e(t)] \\ \times \exp \left\{ \int_0^t [h^*(u) + h(u)e(u)] du \right\} \quad (13)$$

For simplicity, we assume that death times are recorded in years and identify the range of T as $1, 2, \dots, 110, \dots$. Let h_t be the lung cancer mortality rate, h_t^* be the overall mortality rate for age-group t in an unexposed population, and e_t be the ERR for lung cancer mortality in an exposed population for age-group t . Then, the death rates in the exposed population are given by $h_t + h_t e_t$ for lung cancer and $h_t^* + h_t e_t$ for all causes including lung cancer. The discrete-time version of equations (12) and (13) are given as follows:

$$S_t = \Pr\{T \geq t\} = \prod_{l=1}^{t-1} \{1 - (h_l^* + h_l e_l)\} \\ \approx \exp \left\{ - \sum_{l=1}^{t-1} (h_l^* + h_l e_l) \right\} \quad (14)$$

and

$$R_t = \Pr\{T = t\} = (h_t + h_t e_t) S_t \quad (15)$$

The approximation in equation (14) is highly accurate and will be treated as exact in what follows. Substituting equation (14) into equation (15),

the age-specific death rate due to lung cancer in the exposed population is given by

$$R_t = (h_t + h_t e_t) \exp \left\{ - \sum_{l=1}^{t-1} (h_l^* + h_l e_l) \right\} \quad (16)$$

Assuming a maximum lifespan of 110 years, the lifetime lung cancer risk is given by the sum of the annual risks:

$$R = \sum_{t=1}^{110} R_t = \sum_{t=1}^{110} (h_t + h_t e_t) \\ \times \exp \left\{ - \sum_{l=1}^{t-1} (h_l^* + h_l e_l) \right\} \quad (17)$$

In the unexposed population, the $\{e_i\}$ are assumed to be zero, so that

$$R_0 = \sum_{t=1}^{110} h_t \exp \left\{ - \sum_{l=1}^{t-1} h_l^* \right\} \quad (18)$$

Note that the evaluation of the lifetime risk R in equation (17) depends on the excess relative lung cancer risks $\{e_i\}$ within each of the age-groups. The LRR is the ratio of the lifetime risk in the exposed population in relation to that in the unexposed population:

$$LRR = \frac{R}{R_0} \quad (19)$$

Other risks such as population-attributable risks can be characterized using the functional relationship between the risk factors. Using full characterization, the mean LRR is found to be 1.001 and the 95% CI is 1.008–1.578.

Discussion

Although expert opinion is still an important and integral part of risk assessment and risk management, risk assessment can no longer rely solely on unsubstantiated expert opinion as a form of risk assessment. Here we have summarized a general framework for the characterization of risk as a function of risk factors. In this probabilistic assessment, risk factors are considered as random variables with one or two layers of distributional assumptions. Using these distributions, we can not only estimate the risk for specific subset

of the population, but we can also provide confidence intervals.

As we have demonstrated in two examples, risk can be estimated for any population subset. The accuracy of the results largely depends on the functional relationship between risk factors and risk. Thus the distributional form and values of the parameters are also subject to criticism. Given these limitations, we still believe that a probabilistic risk assessment is required to move forward in this field.

Acknowledgments

This research was supported in part by the Cancer Center Support CA21765 from the National Institutes of Health and by the American Lebanese Syrian Associated Charities (ALSAC). The author thanks Dr. A Tyagi for expert suggestions and Dr. Angela McArthur for critical scientific editing. The author is also grateful to the Editor and a referee for providing many helpful suggestions that significantly improved the chapter.

Risk Classification in Nonlife Insurance

Within the actuarial profession, a major challenge can be found in the construction of a fair tariff structure. In light of the heterogeneity within, for instance, a car insurance portfolio, an insurance company should not apply the same premium for all insured risks. Otherwise the so-called concept of adverse selection will undermine the solvability of the company. The idea behind risk classification is to split an insurance portfolio into classes that consist of risks with a similar profile and to design a fair tariff for each of them. Classification variables, typically used in motor third-party liability insurance, are the age and gender of the policyholder and the type and use of their car.

Being able to identify important risk factors is an important skill for the nonlife actuary. When these explanatory variables contain *a priori* correctly measurable information about the policyholder (or for instance, the vehicle or the insured building), the system is called an *a priori classification scheme*. However, an *a priori* system will not be able to identify all important factors because some of them cannot be measured or observed. Think, for instance, of aggressiveness behind the wheel or the swiftness of reflexes. Thus, despite the *a priori* rating system, tariffication cells will not be completely homogeneous. For that reason, an *a posteriori* rating system will reevaluate the premium by taking the history of claims of the insured into account.

Owing to the quantitative nature of both *a priori* and *a posteriori* rating, one of the primary attributes of an actuary (see **Actuary**) should be the successful application of up-to-date statistical techniques in the analysis of insurance data. Therefore, this article highlights current techniques involved in this area of actuarial statistics. The article introduces basic concepts, illustrates them with real-life actuarial data and summarizes references to complementary literature. Examples of likelihood-based as well as Bayesian estimation are included where the latter has the advantage that it provides the analyst with the full predictive distribution of quantities of interest.

Remark 1: Link with statistical techniques for loss reserving The statistical techniques discussed here in the context of risk classification (see **Risk**

Classification/Life Risk Measures and Economic Capital for (Re)insurers), also provide a useful framework for a stochastic approach of the loss reserving problem (see **Nonlife Loss Reserving**) in actuarial science. In this context, the data are displayed in a traditional run-off triangle or variations of it. See [1] and [2] for connections with reserving techniques.

Regression Models for *a priori* Risk Classification

In order to build a tariff that reflects the various risk profiles in a portfolio in a reasonable way, actuaries will rely on regression techniques. Typical response variables involved in this process are the number of claims (or the claims frequency) on the one hand and its corresponding severity (i.e., the amount the insurer will have to pay, given that a claim occurred) on the other hand.

Generalized Linear Models

The history of generalized linear models (GLMs) in actuarial statistics goes back to the actuarial illustrations in the standard text by McCullagh and Nelder [3]. See [4] for an overview in actuarial science. GLMs extend the framework of general (normal) linear models to the class of distributions from the exponential family. A whole variety of possible outcome measures (like counts, binary, and skewed data) can be modeled within this framework. This paper uses the canonical form specification of densities from the exponential family, namely,

$$f(y) = \exp\left(\frac{y\theta - \psi(\theta)}{\phi} + c(y, \phi)\right) \quad (1)$$

where $\psi(\cdot)$ and $c(\cdot)$ are known functions, θ is the natural and ϕ the scale parameter. Members of this family, often used in actuarial science, are the normal, the Poisson, the binomial, and the gamma distribution. Instead of a transformed data vector, GLMs model a transformation of the mean as a linear function of explanatory variables. In this way,

$$g(\mu_i) = \eta_i = (\mathbf{X}\boldsymbol{\beta})_i \quad (2)$$

where $\boldsymbol{\beta} = (\beta_1, \dots, \beta_p)'$ contains the model parameters and $\mathbf{X}$ ($n \times p$) is the design matrix, g is

the link function, and η_i is the i th element of the so-called linear predictor. In a likelihood-based approach, the unknown but fixed regression parameters in β are estimated by solving the maximum-likelihood equations with an iterative numerical technique (such as Newton–Raphson). In a Bayesian approach, priors are assigned to every parameter in the model specification and inference is based on samples generated from the corresponding full posterior distributions.

Illustration 1: Poisson regression for claims frequencies. For detailed case studies on Poisson regression for claim counts, [5] and [6] contain nice examples.

Flexible, Parametric Families of Distributions and Regression

Modeling the severity of claims as a function of their risk characteristics (given as covariate information) might require statistical distributions outside the exponential family, distributions with a heavy tail, for instance. Principles of regression within such a family of distributions are illustrated here with the Burr XII and the GB2 (“generalized beta of the second kind”) distribution. More details on Burr regression are in [7] and for GB2 regression [8] and [9] are useful.

Illustration 2: Fire insurance portfolio. The cumulative distribution function for the Burr type XII and the GB2 distribution are given by

$$F_{\text{Burr},Y}(y) = 1 - \left(\frac{\beta}{\beta + y^\tau} \right)^\lambda, \quad y > 0, \beta, \lambda, \tau > 0 \quad (3)$$

$$F_{\text{GB2},Y}(y) = B \left(\frac{(y/b)^a}{1 + (y/b)^a}; \gamma_1, \gamma_2 \right), \quad y > 0, a \neq 0, b, \gamma_1, \gamma_2 > 0 \quad (4)$$

where $B(\cdot, \cdot)$ is the incomplete beta function. Say, the available covariate information is in $\mathbf{x}$ ($1 \times p$). By allowing one or more of the parameters in equation (3) or equation (4) to vary with $\mathbf{x}$, a Burr or GB2 regression model is built. To illustrate this approach, consider a fire insurance portfolio (see [7]) that consists of 1823 observations. We want to assess how the loss distribution changes with the sum insured and the type of building. Claims expressed as a fraction of the sum insured are used as the response. Explanatory variables are the type of building and the sum insured. Parameters are estimated with maximum likelihood. Residual QQplots like those in Figure 1 can be used

Figure 1 Fire insurance portfolio: residual QQplots for Burr and GB2 regression

to judge the goodness of fit of the proposed regression models. Beirlant *et al.* [7] explains their construction.

A *posteriori* Ratemaking

To update the *a priori* tariff or to predict future claims when historical claims are available over a period of insurance, actuaries can use statistical models for longitudinal or panel data (i.e., data observed on a group of subjects, over time). These statistical models (also known as *mixed models* or *random-effects models*) generalize the so-called credibility models from actuarial science. Bonus–malus systems (see **Bonus–Malus Systems**) for car insurance policies are another example of a *posteriori* corrections to *a priori* tariffs: insured drivers reporting a claim to the company will get a malus, causing an increase of their insurance premium in the next year. More details are, for instance, in [6].

The credibility ratemaking problem is concerned with the determination of a risk premium that combines the observed, individual claims experience of a risk and the experience regarding related risks. The framework of our discussion of this *a posteriori* rating scheme is the concept of generalized linear mixed models (GLMMs). For a historical, analytical discussion of credibility, [10] is a good reference. References [11–15] will provide additional background. References [16–18] discuss explicitly the connection between actuarial credibility schemes and (generalized) linear mixed models and contain more detailed examples. Reference [19] provides yet another statistical approach using copulas instead of random effects.

GLMMs extend GLMs by allowing for random, or subject-specific, effects in the linear predictor. Say we have a data set at hand consisting of N policyholders. For each subject i ($1 \leq i \leq N$) n_i observations are available. These are the claims histories. Given the vector $\mathbf{b}_i$ with the random effects for subject (or cluster) i , the repeated measurements $Y_{i1}, \dots, Y_{in_i}$ are assumed to be independent with a density from the exponential family

$$f(y_{ij}|\mathbf{b}_i, \boldsymbol{\beta}, \phi) = \exp\left(\frac{y_{ij}\theta_{ij} - \psi(\theta_{ij})}{\phi} + c(y_{ij}, \phi)\right),$$

$$j = 1, \dots, n_i \quad (5)$$

The following (conditional) relations then hold

$$\mu_{ij} = E[Y_{ij}|\mathbf{b}_i] = \psi'(\theta_{ij}) \quad (6)$$

and

$$\text{Var}[Y_{ij}|\mathbf{b}_i] = \phi\psi''(\theta_{ij}) = \phi V(\mu_{ij}) \quad (7)$$

where $g(\mu_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta} + \mathbf{z}'_{ij}\mathbf{b}_i$, $g(\cdot)$ is called the *link*, and $V(\cdot)$ the *variance function*. $\boldsymbol{\beta}$ ($p \times 1$) denotes the fixed effects parameter vector and $\mathbf{b}_i$ ($q \times 1$) the random effects vector. $\mathbf{x}_{ij}$ ($p \times 1$) and $\mathbf{z}_{ij}$ ($q \times 1$) contain subject i 's covariate information for the fixed and random effects, respectively. The specification of the GLMM is completed by assuming that the random effects, $\mathbf{b}_i$ ($i = 1, \dots, N$), are mutually independent and identically distributed with density function $f(\mathbf{b}_i|\boldsymbol{\alpha})$. Hereby $\boldsymbol{\alpha}$ denotes the unknown parameters in the density. Traditionally, one works under the assumption of (multivariate) normally distributed random effects with zero mean and covariance matrix determined by $\boldsymbol{\alpha}$. The random effects $\mathbf{b}_i$ represent unobservable, individual characteristics of the policyholder. Correlation between observations on the same subject arises because they share the same random effects. Reference [18] provides a discussion of likelihood-based and Bayesian estimation (see **Mathematics of Risk and Reliability: A Select History**) for GLMMs; with references to the literature and worked-out examples.

Illustration 3: Workers' compensation insurance. The data are taken from [20]. A total of 133 occupation or risk classes are followed over a period of 7 years. Frequency counts in workers' compensation insurance are observed on a yearly basis. Possible explanatory variables are **Year** and **Payroll**, a measure of exposure denoting scaled payroll totals adjusted for inflation. The following models are considered

$$Y_{ij}|\mathbf{b}_i \sim \text{Poisson}(\mu_{ij}) \quad (8)$$

where

$$\log(\mu_{ij}) = \log(\text{Payroll}_{ij}) + \beta_0 + \beta_1 \text{Year}_{ij} + b_{i,0} \quad (9)$$

versus

$$\log(\mu_{ij}) = \log(\text{Payroll}_{ij}) + \beta_0$$

$$+ \beta_1 \text{Year}_{ij} + b_{i,0} + b_{i,1} \text{Year}_{ij} \quad (10)$$

Table 1 Workers' compensation data (frequencies): results of maximum likelihood and Bayesian analysis. $\delta_0 = \text{Var}(b_{i,0})$, $\delta_1 = \text{Var}(b_{i,1})$, and $\delta_{0,1} = \delta_{1,0} = \text{Cov}(b_{i,0}, b_{i,1})$

Hereby, Y_{ij} represents the j th measurement on the i th subject of the response Count. β_0 and β_1 are fixed effects and $b_{i,0}$, versus $b_{i,1}$, is a risk class specific intercept, versus slope. It is assumed that $\mathbf{b}_i = (b_{i,0}, b_{i,1})' \sim N(\mathbf{0}, \mathbf{D})$ and that, across subjects, random effects are independent. The results of both a maximum likelihood (penalized quasi-likelihood and adaptive Gauss–Hermite quadrature) and a Bayesian analysis are given in Table 1. The models were fitted to the data set without the observed Count_{*i*7}, to enable out-of-sample prediction later on. To illustrate prediction with model (10), Table 2 compares the predictions for some selected risk classes with the observed values. Predictive distributions obtained with a Bayesian analysis are illustrated in Figure 2.

Zero-Inflated, Additive, and Spatial Regression Models for *a priori* and *a posteriori* Ratemaking

This section contains references to some more advanced regression techniques for both cross-

sectional data (i.e., one observation per subject, as in section titled “Regression Models for *a priori* Risk Classification”) and panel data.

Dealing with regression models for claim counts, the huge number of zeros (i.e., no claim events) is often apparent. For data sets where the inflated number of zeros causes a bad fit of the regular Poisson or negative binomial distribution, zero-inflated regression models [21] provide an alternative. See [22] for a discussion of zero-inflated regression models for *a priori* classification schemes for count data.

In the modeling of severity data that consist of exact zeros and strictly positive payments, so-called two-part regression models are often used. They specify separate regression models for $Y = 0$ and $Y > 0$. See [2] for an illustration.

So far, only regression models with a linear structure for the mean or a transformation of the mean have been discussed. To allow for more flexible relationships between a response and a covariate, generalized additive models (GAMs) are available, see e.g. [2] for several actuarial examples. When the

Figure 2 Workers' compensation insurance (counts): predictive distributions for selection of risk classes

place of residence of a policyholder is available as covariate information, spatial regression models (*see Statistics for Environmental Toxicity Geographic Disease Risk*) allow to bring this into account. See [23] for an illustration with spatial GAMs for cross-sectional observations on claim counts and severities.

Evidently, the mixed models for *a posteriori* ratemaking discussed above can be extended to zero-inflated, generalized additive mixed models (GAMMs) and spatial models to allow for more flexibility in model building. See e.g. [2] for an example with GAMMs.

KATRIEN ANTONIO AND JAN BEIRLANT

Risk Classification/Life

Risk Pooling, Heterogeneity, Risk Factors

The traditional principle of insurance management, the pooling of risks (*see* **Dependent Insurance Risks; Correlated Risk**), relies on the availability of a large number of similar insured lives, so that there is a high probability that the actual outcome in the portfolio is close to what was expected. In a properly managed insurance business, individual policies are important not by themselves but in terms of the risk sharing opportunities, which they provide to the portfolio.

Insurance companies use the underwriting process to select the lives to be insured and to detect differences among the insureds, given that unidentified heterogeneity introduces biases, which will undermine the realization of the pooling effect.

As a result of the underwriting process, policies are usually grouped according to the different levels of the important aspects affecting mortality, the so-called risk factors. A specific premium rate is then calculated for each group, which is in particular based on a sound set of mortality rates (*see* **Pricing of Life Insurance Liabilities; Estimation of Mortality Rates from Insurance Data**).

When referring to life insurance, among the major risk factors, we can list [1] the following:

1. biological and physiological factors, such as age, gender, genotype;
2. features of the living environment, in particular with regard to climate and pollution, nutrition standards (in particular, excesses and deficiencies in diet), population density, and hygienic and sanitary conditions;
3. occupation, in particular in relation to exposure to injury or adverse conditions, and educational attainment;
4. individual lifestyle, in particular with regard to nutrition, alcohol and drugs consumption, smoke, physical activities, and pastimes;
5. current health conditions, personal and/or family medical history, civil status, and so on.

Item 2 above affects the overall mortality of the population living in a given region. As such, it is not an explicit risk rating variable; it is only implicitly

considered given that the mortality table referred to for insurance rating in a market usually reflects the general features of mortality in the relevant region (*see* **Individual Risk Models**). The remaining items concern the individual and, when dealing with life insurance, they can be observed at policy issue. Their assessment is performed through questions in the application form and, as to personal health conditions, possibly through a medical examination.

The specific items considered for rating depend on the types of benefits provided by the insurance contract. Age is always considered, and can be traced back to the introduction of scientific life insurance by Dodson in 1756 [2]. Thus the probability of dying within 1 year for a person aged x (also called the *mortality rate*) is usually denoted as q_x . Gender is usually accounted for, especially when living benefits are involved, given that females on average live longer than males. In this regard, distinct mortality tables for males and females are normally adopted. As far as genetic aspects are concerned, the evolving knowledge in this area has raised a lively debate (which is still open) on whether it is legitimate for insurance companies to resort to genetic tests for underwriting purposes. So far, this aspect has not entered the rating process.

A distinctive phenomenon in insurance is adverse selection (or self-selection). Adverse selection is the “tendency of high risks to be more likely to buy insurance or to buy larger amounts of insurance than low risks” [3]. An individual has a level of insurance risk and a particular level of demand for insurance, which may be correlated with the risk level, and which itself may be influenced by a range of factors. The presence of adverse selection provides the conventional economic argument in favor of underwriting and risk classification. Thus, those individuals applying for living benefits are usually in good health conditions, while those buying a death benefit may be in poor health conditions. In both cases, the mortality experienced by a life insurer may be different from the mortality observed in the general population, in particular lower in the former case of living benefits, higher in the latter case of death benefits. For this reason, a thorough investigation is conducted to check individual health conditions when death benefits are involved. Clearly, the level of accuracy of such an investigation depends on the amounts of insurance involved (*see* **Dynamic Financial Analysis**).

When death benefits are dealt with, the main risk factors considered are health conditions, occupation, and smoking status. According to the level of these factors, the risks are classified into standard and substandard risks. For the latter (also referred to as impaired lives or extra risks), a higher premium rate is adopted, given that they have a higher probability of becoming eligible for the benefit. In some markets, the standard risks are further split into regular and preferred risks, the latter having a better profile than the former (for example, because they have never smoked); as such, the latter are allowed to pay a reduced premium rate.

As far as annuities and living benefits are concerned, adverse selection leads to reduced mortality rates (relative to the general population) and these are adopted for rating annuities. There is also evidence that mortality rates are lower for annuity products (see **Longevity Risk and Life Annuities**) where the purchase is voluntary rather than compulsory. In recent years, market innovations have led to the introduction of special (i.e., favorable) annuity prices for those lives assessed to have reduced life expectancies (as introduced into the UK market in 1995).

A similar approach to assessment of risk factors and underwriting takes place in the growing areas of disability, health, critical illness, and long-term care insurance [4].

Differential Mortality

The mortality experienced by people in poorer or better conditions than the average is usually expressed in relation to average (or standard) mortality. This allows us to deal only with one mortality table (or law), from which both normal and adjusted premium rates for substandard or preferred risks may be obtained. In the case of annuities and pensions, usually specific tables are constructed, which allow for both adverse selection and the secular downward trend in mortality rates at adult and old ages. This latter feature is incorporated in order to avoid the underestimation of future costs.

Let us index with (S) a quantity expressing standard mortality and with (D) a quantity expressing a different (higher or lower) mortality. According to the usual notation, $q_x^{(S)}$ denotes the mortality rate at age x (either for a male or a female), while $\mu_x^{(S)}$ represents the force of mortality at age x (also in this

case gender-specific); further, we understand that x is the current age and t is the time elapsed since policy issue ($t \geq 0$). The following are examples of models expressing differential mortality, i.e., mortality for either substandard risks, preferred lives or annuitants (details are provided below).

$$q_x^{(D)} = a q_x^{(S)} + b \quad (1)$$

$$\mu_x^{(D)} = a \mu_x^{(S)} + b \quad (2)$$

$$q_x^{(D)} = q_{x+k}^{(S)} \quad (3)$$

$$\mu_x^{(D)} = \mu_{x+k}^{(S)} \quad (4)$$

$$q_x^{(D)} = \psi(x, q_x^{(S)}) \quad (5)$$

$$q_x^{(D)} = q_x^{(S)} \cdot \phi(x) \quad (6)$$

$$q_{[x-t]+t}^{(D)} = \rho(x-t, t) \cdot q_x^{(S)} \quad (7)$$

$$q_{[x-t]+t}^{(D)} = q_{[x-t]}^{(S)} \cdot \nu(t) \quad (8)$$

$$q_{[x-t]+t}^{(D)} = q_{[x-t]+t}^{(S)} \cdot \eta(x, t) \quad (9)$$

Models (1) and (2) are usually adopted for substandard risks; adoption of equation (1) or equation (2) depends on the information available for standard mortality, either a mortality table or the parameters of a given law for the force of mortality. Letting $a = 1$ and $b = \delta q_{x-t}^{(S)}$, $\delta > 0$, in equation (1) ($b = \delta \mu_{x-t}^{(S)}$ in equation (2)) the so-called additive model is obtained, where the increase applied to mortality depends on the initial age and, for a given individual, is therefore constant. An alternative model is obtained by choosing $b = \theta$, $\theta > 0$, in equation (2), i.e., a mortality increase that is constant and independent of the initial age; such a model is consistent with extra mortality due to accidents (related, for example, either to occupation or the extreme sports). Letting $a = 1 + \gamma$, $\gamma > 0$, and $b = 0$ the so-called multiplicative model is derived, where the mortality increase depends on current age and therefore changes (typically, increases) with time; in the case of equation (2), this model is widely known as the “proportional hazards” model. When risk factors are only temporarily effective (for example, extra mortality due to some diseases, which either lead to an early death or recovery in a short time), parameters a , b may be positive up to some proper time τ ; and for $t > \tau$, standard mortality is assumed, so that $a = b = 0$.

Models (3) and (4) are very common in practice, both for substandard and preferred risks, due to their

simplicity; they are called *age rating* or *age shifting models*. Assuming, as is evidenced by mortality experience, that after some (young) age mortality rates (and the force of mortality, as well) are increasing with respect to age, the idea is to assign, for rating purposes, an older initial age to substandard risks and a younger initial age to preferred lives. This adjustment process results in a higher (lower) premium rate. Model (4), in particular, can be formally justified if the standard force of mortality is driven by the Gompertz law. Actually, let $\mu_x^{(S)} = \beta \cdot c^x$. Assume the multiplicative model for differential mortality. Then we have $\mu_x^{(D)} = (1 + \gamma) \cdot \beta \cdot c^x$. Let k be the real number (unambiguously defined) such that $1 + \gamma = c^k$. We obtain

$$\mu_x^{(D)} = \beta \cdot c^{x+k} = \mu_{x+k}^{(S)} \quad (10)$$

Adoption of equation (4) under laws other than the Gompertz or the adoption of model (3) represent rules that are not formally justified, albeit supported by equation (10). In actuarial practice, sometimes the age shifting is also applied directly to the premium rate.

In equations (5) and (6), mortality is adjusted in relation to age. Such a choice is common when annuities are dealt with. For example, $\phi(x)$ may be a step-wise linear function, with $\phi(x) < 1$. In such an application, $q_x^{(S)}$ describes mortality in the general population (usually projected, i.e., embedding a forecast of future trends), while $\phi(x)$ is a reduction factor accounting for self-selection.

The notation $q_{[x-t]+t}^{(\cdot)}$ is usually adopted when mortality depends not only on current age, x , but also on the time elapsed since policy issue, t . Such dependence is, in particular, observed in portfolios of death benefits; because of the medical selection, insured risks may experience better mortality than the average in initial years. Such dependence is also occasionally observed in annuity portfolios. The effect tends to reduce as time passes on. So we expect $q_{[x]}^{(\cdot)} < q_{[x-1]+1}^{(\cdot)} < \dots$. Mortality rates $q_{[x-t]+t}^{(\cdot)}$ are called *issue-select*, while the $q_x^{(\cdot)}$'s (dependent on current age only) are the so-called *aggregate mortality rates*. Model (7) expresses issue-select mortality in terms of aggregate mortality; typically, $\rho(x - t, t) < 1$, and so, it represents a reduction factor. Sometimes, for $t \geq \tau$ (where τ represents the length of the period in which initial selection affects mortality) the reduction factor is simply adopted dependent on current age,

i.e., $\rho(x - t, t) = \tilde{\rho}(x)$. Models (8) and (9) express issue-select differential mortality through a transform of the issue-select standard mortality rates. In particular, $v(x)$ and $\eta(x, t)$ may be chosen to be linear.

For details on the models listed above, as well as on more specific models, the reader may refer for example, to [1].

A particular implementation of model (1) (with $b = 0$) is given by the so-called “numerical rating system”, introduced in 1919 by New York Life Insurance and still adopted by many insurers [5]. If we assume that there is a set of m risk factors, then the mortality rate specific for a given individual is

$$q_x^{(\text{spec})} = q_x^{(S)} \cdot \left(1 + \sum_{h=1}^m \rho_h \right) \quad (11)$$

where the rates ρ_h lead to a higher or lower mortality rate for the individual in relation to the values assumed by the chosen risk factors (clearly, $\sum_{h=1}^m \rho_h > -1$). Note that an additive effect of the risk factors is assumed. For further details, see [3].

The Frailty

Once policies have been grouped according to the different levels of the relevant risk factors, there is still heterogeneity within the groups (*see Life Insurance Markets*). Such heterogeneity may be due both to risk factors which, for commercial reasons, have not been considered for rating purposes and to features attributable to unobservable risk factors (such as, for example, the individual's attitude towards health, the congenital propensity to survive or die or to become ill). In respect of the latter set Vaupel *et al.* [6] have introduced the idea of frailty, which is defined as a nonnegative quantity whose level expresses the unobservable risk factors affecting individual mortality. The underlying idea is that those with higher frailty die on average earlier than others. The mortality model (*see Hazard and Hazard Ratio; Logistic Regression*) is specified in terms of the force of mortality.

Let us refer to a cohort, which is homogeneous in respect of observable risk factors, but heterogeneous because of the different individual levels of frailty. The specific value of the frailty of the individual does not change in time, while remaining unknown. However, because of the deaths that

occur, the distribution of people with regard to frailty changes with age, given that people with low frailty are expected to live longer. We denote with Z_x the relevant random variable at age x , for which a continuous density function $g_x(z)$ is assumed. It must be mentioned that the hypothesis of constant individual frailty, which is reasonable when considering genetic aspects, seems weak when referring to environmental factors, which may change in time affecting the risk of death. However, empirical evidence does validate this assumption quite satisfactorily.

For a person of current age x and frailty level z , the force of mortality is defined as

$$\mu_x(z) = \lim_{t \rightarrow 0} \frac{\Pr(T_x \leq t | Z_x = z)}{t} \quad (12)$$

where, according to standard notation, T_x represents the random lifetime at age x .

A very simple link between $\mu_x(z)$ and a standard force of mortality is a multiplicative relation, as suggested by Vaupel *et al.* [6]. If μ_x represents the standard force of mortality, we can assume

$$\mu_x(z) = z \cdot \mu_x \quad (13)$$

Note that if $z > 1$ ($z < 1$) then $\mu_x(z) > \mu_x$ ($\mu_x(z) < \mu_x$). An individual with $z = 1$ has a standard mortality profile, while those with higher (lower) frailty bear a higher (lower) probability of early death.

The complete definition of the mortality model requires (a) the density function of the frailty at age 0 and (b) the law of the force of mortality. For full details, the reader should refer to [6]; here we just comment on some of the main results relevant for insurance applications.

The distribution of the frailty changes with time (i.e., with increasing age) because of the varying composition of the cohort due to deaths. Thanks to the multiplicative assumption in equation (13), the density function of Z_x can be derived from that of Z_0 by noting that $Z_x = Z_0 | T_0 > x$. Let $S(x|z)$ denote the survival function for a person with frailty z ; similarly to the standard valuation, we have

$$S(x|z) = e^{-\int_0^x \mu_t(z) dt} = e^{-z \int_0^x \mu_t dt} \quad (14)$$

It is easy to derive the following result for the density function of Z_x

$$g_x(z) = \frac{S(x|z) \cdot g_0(z)}{\int_0^\infty S(x|z) \cdot g_0(z) dz} \quad (15)$$

The expected frailty at age x is

$$\bar{z}_x = \int_0^\infty z g_x(z) dz \quad (16)$$

If we define the average force of mortality in the population at age x as

$$\bar{\mu}_x = \int_0^\infty \mu_x(z) \cdot g_x(z) dz \quad (17)$$

then it can be shown that, under the assumptions introduced above,

$$\bar{\mu}_x = \mu_x \cdot \bar{z}_x \quad (18)$$

Let us comment on the above-mentioned results in relation to possible insurance applications. First of all, it should be stressed that the frailty model does not provide us with a specific premium rate for each individual (due to the unknown individual frailty level); rather, some information concerning the aggregate mortality in a heterogeneous cohort (*viz* $\bar{\mu}_x$) can be obtained.

We note that the average frailty $\bar{z}_x$ is decreasing with age (this can be shown formally, but it is an intuitive result, due to the fact that those with a high frailty die earlier). This implies that, from a given (young) age onwards $\bar{\mu}_x$ increases with age but more slowly than the standard force of mortality μ_x . So, in an insured portfolio, where risks are selected through the underwriting process or are self-selected (especially in the case of life annuities), one should expect mortality experience to be on average lower than that observed in the general population. This is why, when living benefits are dealt with, reduction factors should be applied to the mortality rates relating to the general population, as was mentioned earlier. In the case of death benefits, adoption of mortality tables relating to the general population leads to the inclusion of a safety loading in premium rates for standard risks.

A further issue, relevant when life annuities are dealt with, concerns the shape of mortality rates in a given population at the oldest ages. When referring to

a time-continuous setting, the usual assumption in life insurance is that the (standard) force of mortality is exponential with respect to age (typically, a Gompertz or Makeham model is adopted). If one disregards the changing distribution of frailty in a group of people, then the exponential assumption relates to any age. When allowing for frailty, different conclusions may be obtained. For example, if one assumes a gamma distribution for the frailty and the Gompertz model for the standard force of mortality, then the following result holds for the average force of mortality:

$$\bar{\mu}_x = \frac{\beta c^x}{1 + \delta c^x} \quad (19)$$

where parameters β , δ , c are properly defined in terms of the parameters adopted for the gamma distribution and the Gompertz law. It must be stressed that according to equation (19) the average force of mortality in the group has a logistic shape. In particular, this affects the shape of mortality at the oldest ages, which is flatter than otherwise assumed.

Several generalizations of the original frailty model described by Vaupel *et al.* [6] have been discussed in demographic literature. For some investigations concerning mortality in insured portfolios, see in particular [7], where possible extensions to the basic frailty model are recalled.

We finally mention an alternative procedure to obtain equation (19), which is interesting within the insurance area, due to its similarity to the Poisson gamma model used for detecting heterogeneity in nonlife insurance portfolios. We refer to a population where the force of mortality for an individual, $\mu_x^{(\cdot)}$, is Gompertz-like; more specifically, we assume

$$\mu_x^{(\cdot)} = A \cdot c^x \quad (20)$$

where the parameter c , expressing the rate of mortality increase in respect of age, is known and common to all individuals, while the parameter A , expressing

base mortality, is unknown and specific to the life considered. If $f(\alpha)$ is the density function of A , then the average force of mortality in the population can be calculated as

$$\bar{\mu}_x = \int_0^\infty \alpha \cdot c^x \cdot f(\alpha) d\alpha = c^x \cdot E(A) \quad (21)$$

If a gamma distribution is assumed for A , with parameters such that $E(A) = \beta/(1 + \delta c^x)$, then equation (19) follows. This procedure was first described by Beard [8]; see also [3] for further details.

STEVEN HABERMAN AND ANNAMARIA
OLIVIERI

Risk from Ionizing Radiation

Radiation risk commonly refers to *ionizing* radiations: energetic photons such as γ and X rays and various accelerated subatomic particles such as alphas, betas, and neutrons, in contrast to other, non-ionizing forms of directed energy such as electromagnetic radiations with quantum energies less than about 1000 eV (i.e., wavelength greater than about 1 nm) [1], sonic energy, etc. Humans are exposed to ionizing radiation from a number of sources: natural background radiation (including *radon* (see **Radon**)), medical diagnosis and therapy, nuclear power generation, occupations involving radioactive materials (mining, nuclear workers, hospital, laboratory technologists and radiologists, etc.), nuclear weapons testing, and occasional accidents. Because radon is covered separately in this encyclopedia, we do not address that area of research here.

The ionizing radiations share fundamentally important biophysical properties from the nature of the damage to living organisms that can originate with ionization of molecules in cells. The nonionizing radiations in contrast are typically treated separately according to category: i.e., microwave *versus* ultraviolet radiation, etc. and involve different possible biophysical mechanisms. Since the early decades of the twentieth century, ionizing radiations have been associated, through animal experiments and human experience with accidental or (originally) poorly understood excessive doses, with damage to tissue, genetic mutations, and neoplastic lesions including cancer. Studies of radiation effects are based on *radiation dose* received by tissues of affected individuals: the amount of ionizing energy deposited per unit mass of tissue; a basic unit is $1 \text{ Gy} = 1 \text{ J kg}^{-1}$. Among ionizing radiations, some create much more closely spaced ionizations at a microscopic level than others: heavier particulate radiations such as neutrons and alphas are much more densely ionizing than electrons and γ rays. A radiation's density of ionization, or "quality," as quantified by linear energy transfer (LET), characteristic of its type and energy, is strongly associated with its biological effect per unit dose (radiobiological effectiveness, RBE). The estimation of radiation dose (radiation dosimetry) for

major health effects studies was recently reviewed in a special issue of *Radiation Research* [2].

Effects of ionizing radiation have typically been divided broadly into acute effects and late effects. Acute effects are nonstochastic outcomes that occur with certainty but have a *severity* that depends on the radiation dose, although there is typically a practical dose threshold, below which the severity is not sufficient to be distinguished from no effect, and there is variation in radiosensitivity among individuals. In contrast, most late effects are seen as stochastic events that occur with a *probability* that depends on radiation dose, among many other covariates. Acute effects are forms of morbidity due to cell killing and are mainly of interest at higher doses. As "risk assessment" generally denotes evaluating the probability of stochastic late effects rather than the likely severity of acute effects, we focus here on late effects. These do not have any unique attributes associated with the involvement of radiation in their etiology, and can only be discerned statistically as increased rates associated with exposure in studies on groups of people with varying exposure. The effect of a covariate such as attained age or age at exposure, on the risk of a stochastic effect per unit radiation dose, is termed *risk modification*. Most work has focused on cancer and other neoplastic diseases such as leukemia, along with genetic effects, although some has been aimed at other effects such as nonspecific life span shortening. More recently, the occurrence of chronic diseases other than cancer has been associated as a late effect with ionizing radiation [3]. A few outcomes, such as cataract, have aspects of both acute and late effects.

Radiation Risk Estimation

Estimates of radiation risk are based upon epidemiologic studies of populations exposed to ionizing radiation: the atomic bomb (A-bomb) survivors, persons exposed medically or occupationally (particularly nuclear industry workers and radiologists/radiological technologists), and persons exposed environmentally (e.g., high-background areas, areas near the Chernobyl nuclear reactor, and areas affected by large releases of radioactive material from nuclear weapons production and testing). See biological effects of ionizing radiation BEIR VII [3] and United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) 2000 [4] for complete listings. These

studies involve a wide range of radiations, doses, and configurations (whole body *versus* localized exposure; acute *versus* chronic or protracted exposure). In all of these studies, the usual epidemiologic considerations of comparison population and counterfactual hypotheses apply [5]. The A-bomb survivor follow-up study of approximately 120 000 individuals in Hiroshima and Nagasaki, Japan, who were exposed acutely to primarily γ rays, constitutes the longest follow-up study on late effects of radiation and arguably the most informative analysis of radiation risk in terms of assessing risk modification and investigating causal mechanisms. Even in that study, inference on risk is sensitive to choice of an unexposed comparison group from a possible source population that resided over a wide geographic range (urban *versus* rural environment, etc.), within the cities but too distant from the sites of bombs to have an appreciable dose, including 32 000 control persons who were temporarily away from the cities at the time of the bombings [6, 7].

Current analyses of radiation risk rely heavily on ideas originally proposed by Thomas [8], which allow flexibility in modeling the shape of the dose–response. Risk estimation involves not only estimation of a risk coefficient (e.g., relative risk (RR)), but also requires accounting for spontaneous (background) rates of disease or death and assessment of effect modification by age, time, gender, and other factors. Perhaps the most common form of risk model is the *excess relative risk* (ERR) model:

$$r_{\beta}(d, \mathbf{z}) = 1 + \rho_{\beta}(d) \exp(\boldsymbol{\gamma}\mathbf{z}) \quad (1)$$

where $r_{\beta}(d, \mathbf{z})$ is the relative risk, $\rho_{\beta}(d)$ is the ERR at dose d depending on parameter β , and $\exp(\boldsymbol{\gamma}\mathbf{z})$ represents effect modification by factor $\mathbf{z}$ (typically $\boldsymbol{\gamma}\mathbf{z} = \gamma_1 \times \text{gender} + \gamma_2 \times (\text{exposure age}) + \gamma_3 \times (\text{age at risk})$, although time since exposure could be used; note that there are problems in the interpretation of age–time risk modification owing to collinearity among the three age–time scales, see [9]).

The simplest ERR model is the linear ERR model: $\rho_{\beta}(d) = \beta d$ (β is the ERR per unit dose). The RR – the ratio of the hazard of disease or death at nonzero dose to the baseline hazard – is estimated in the context of a *multiplicative model*: $\lambda_{\beta}^{\text{RR}}(\mathbf{t}, \mathbf{s}, d, \mathbf{z}) = \lambda^0(\mathbf{t}, \mathbf{s}) r_{\beta}(d, \mathbf{z})$, with $\mathbf{t}$ being a generic timescale variable denoting both attained age (*age at risk*) and calendar time, $\mathbf{s}$ being a collection of factors impacting the background rate (e.g., gender, geographic location, lifestyle and genetic factors, etc.;

the factors $\mathbf{s}$ and $\mathbf{z}$ can have elements in common), and λ^0 being the baseline hazard.

Another measure of risk often of interest is the excess absolute rate (EAR) of disease or death defined by the *additive model*

$$\lambda_{\varphi}^{\text{EAR}}(\mathbf{t}, \mathbf{s}, d, \mathbf{z}) = \lambda^0(\mathbf{t}, \mathbf{s}) + \rho_{\varphi}(d) \delta(\mathbf{t}, \mathbf{s}, \mathbf{z}) \quad (2)$$

where $\rho_{\varphi}(d) \delta(\mathbf{t}, \mathbf{s}, \mathbf{z})$ is the excess rate and $\rho_{\varphi}(d)$ can be linear [$\rho_{\varphi}(d) = \varphi d$] or otherwise [10]. Because the RR $r_{\beta}(d, \mathbf{z}) \equiv \lambda_{\varphi}^{\text{EAR}}(\mathbf{t}, \mathbf{s}, d, \mathbf{z}) / \lambda^0(\mathbf{t}, \mathbf{s})$, the additive risk model equates to the multiplicative model if the added risk due to radiation has the same functional form with respect to covariates $(\mathbf{t}, \mathbf{s})$ as the baseline risk, i.e., if $\delta(\mathbf{t}, \mathbf{s}, \mathbf{z}) = C \lambda^0(\mathbf{t}, \mathbf{s})$, where C is some constant. Although this is often not the case, as excess rates can depend on age and time in ways that are not proportional to the background rates, given sufficient flexibility in their respective risk-modifying terms the two models are equivalent in terms of goodness of fit to the data, so they merely provide alternative descriptions of the same underlying process. Choice of the model to use in describing the rates is therefore a matter of preference as to how one wishes to describe the radiation effects, and not a matter of statistical model selection. With either model, appropriate modeling of background rates is important for making inference about risk modification (the term $\exp(\boldsymbol{\gamma}\mathbf{z})$ in equation (1) or $\delta(\mathbf{t}, \mathbf{s}, \mathbf{z})$ in equation (2)), because improperly controlled covariate effects on background rates can bias estimates of effect modification [11].

For large cohorts, it is common to estimate risk using the grouped survival approach with Poisson regression [12]. Briefly, if a hazard $\lambda(t)$ can be assumed to be sufficiently small over suitable intervals of age and time conditional on factors $\mathbf{s}$, so that only a fraction of the cohort members are expected to evidence outcome in the interval, it is a reasonable approximation to treat the number of cases of disease or death in age/time/factor stratum i as a Poisson distributed variable with mean $P_i \lambda_i^*(\mathbf{t}_i, \mathbf{s}_i, d_i, \mathbf{z}_i)$, where P_i is the total person time in the stratum, $\mathbf{t}_i$ denotes the person year weighted average age and time values in the stratum, $\mathbf{s}_i$ and $\mathbf{z}_i$ denote the stratum-specific person year weighted average values of background and effect-modifier variables defined above, and the $*$ denotes the piecewise constant rate. Regression analysis of Poisson rate data can be handled using the generalized linear model (GLM) framework with maximum likelihood estimation using iteratively

reweighted least squares (IRLS) [13]. It produces results close to those from continuous-data methods when the piecewise constant hazard assumption is approximately true (i.e., when the strata are sufficiently small the rates do not change appreciably within strata [14]). To accommodate the ERR model nonlinear fitting procedures are required; these are easily accommodated with the *Epicure* software package [15]. The *Epicure* software also allows general modeling of the joint effects of multiple risk factors, including risk modification by factors other than age and time (e.g., smoking; see the next section). Statistical significance of parameter estimates is typically assessed using likelihood ratio tests and likelihood-ratio-based confidence intervals. Goodness of fit may be examined using deviance residuals.

In studies of radiation risk, as with epidemiologic cohort studies in general, there is nonnegligible measurement error (random error or uncertainty) in the exposure estimate. In the A-bomb survivor analyses based on Poisson rate regression, replacement methods assuming classical measurement error have been used [16]; these impute the expected value of true, unknown dose given the measured value and conditional on various assumptions about the error distribution relating true and measured dose as well as the unknown distribution of true dose. Assumptions may be relaxed by using nonparametric methods to estimate the true-dose distribution [17]. Other methods of dealing with measurement error in risk estimation are also available, such as models based on structural equations in which the true, unknown dose can be integrated out of a full likelihood, or the marginal relationship of the measured dose and the outcome can be estimated without explicit modeling of the true, unknown dose, based on certain assumptions (see, e.g. [18]).

Risk estimation may be based alternatively on individual follow-up data, using e.g., Cox regression. A disadvantage of Cox regression is the computing time required with large cohorts having extensive amounts of follow-up time and many failures; this is precisely the situation in which the Poisson approximation is especially good. For smaller cohorts with relatively small total follow-up time the person-year stratification may not be so fine and the assumption that rates do not change appreciably within strata may not hold; with such data, however, the expected number of events will be relatively low so that Cox regression is a tractable approach. Cox regression

also allows the researcher to leave the mathematical structure of background rates unspecified, but this is merely a matter of preference as simple descriptive models in age and time generally capture these effects well with sufficient data. The likelihood for individual data may be extended to include mechanistic models of carcinogenesis such as multistage models [19] and two-stage clonal expansion (TSCE) models [20].

Radioepidemiological Tables and Application of Risk Estimates to Radiation Protection

In addition to ERR or EAR, other quantities are of interest in radiation protection. These include the *excess lifetime risk* and *lifetime detriment* (loss of life expectancy [21]), as well as the *probability of causation* (PC assigned shares, or excess fraction; see “radioepidemiological tables” [22]). Excess lifetime risk – the increase in lifetime probability of death from a particular cause – is complicated by competing causes related to exposure [23]. Radiation protection guidelines are often formulated using measures such as excess lifetime risk. As this integrates over all possible attained ages at expression of the health effect in question, it involves assumptions about the composition of the population to which the standards are to be applied, with respect to the effect-modifier variables defined above; this is an issue more generally in transporting or generalizing risk estimates from a study population to other populations.

Estimation of causal probabilities is not generally possible in epidemiologic studies without strong and untestable assumptions [24]; nevertheless, the primary parameter used to approximate PC is the attributable fraction, $ERR/RR = (RR - 1)/RR = ERR/(1 + ERR)$. In the face of other risk factors, which may interact with radiation, PC should be calculated conditionally on the level of the other factor; this is implemented in the radioepidemiological tables in the case of smoking and lung cancer (see also [25]). With a multiplicative model for joint effect between dose d and another risk factor f , the ERR for exposure d is independent of f [$ERR(d|f) = ERR(d)$], so the PC for radiation does not depend on the other factor. With an additive model, $ERR(d|f) = ERR(d)/[1 + ERR(f)]$, so the PC for radiation depends on the level of the other factor f . As generally occurs in epidemiologic studies, lack of power to discriminate between additive

and multiplicative scales for joint effects (i.e., assess interaction between d and f) means that calculation of PC can be subject to large uncertainty when there is exposure to multiple risk factors [26], but ignoring other factors produces estimates of PC that are not specific to an individual case [27].

Major Results

Assessment of risk from ionizing radiation, perhaps the best studied of all *environmental hazards* (see **Environmental Hazard**), is a classical example of the *low-dose extrapolation* (see **Low-Dose Extrapolation**) problem common to environmental and toxicological risk assessment in general: the primary interest is in risk of exposure to low doses (in particular medical uses and occupations involving radiation exposure), but studies at low dose do not provide adequate statistical power, so results from exposures to high doses must be extrapolated to low doses with appropriate adjustment for other differences such as dose rate. The Japanese A-bomb survivor studies are often considered high-dose studies, but large portions of the survivor population actually received relatively low doses compared to the maximum survivable whole-body dose (the $LD_{50/60}$ – the dose producing 50% mortality in 60 days – is about 3.5–4.0 Gy air or surface dose [28]). The mean dose among A-bomb survivors with dose estimates is about 0.2 Gy but the median dose is only about 0.003 Gy. Current radiation protection standards recommended by the International Commission on Radiological Protection (ICRP) allow a maximum of 0.02 Gy yr^{-1} averaged over 5 years for occupationally exposed persons and a maximum of 0.001 Gy yr^{-1} for the public [29], and there is great interest in the range of total dose below about 0.1 Gy. The problem in the A-bomb cohort is that studies including only doses in this range or below do not have enough fitted excess cases to provide meaningful estimates, and they produce results that depend on the choice of unexposed control group, whereas studies including higher doses depend on both the choice of unexposed control group and the assumed shape of the dose–response [6]. The transport of risk to populations affected by radiation protection guidelines also involves problems of extrapolating to exposures that may be chronic, may involve high-LET radiations, and may involve populations with very different baseline rates of the health effect under consideration.

The major findings so far of the A-bomb survivor studies can be summarized as follows: an early elevated risk of leukemia mortality (albeit on top of a small background or spontaneous rate) that has subsided – though not disappeared altogether – to this day [30], an elevated risk of cancer incidence and mortality later in life that has persisted with slight decline over many decades following the exposure and is inversely related to the age at exposure [10], and an increased risk of mortality from certain diseases other than cancer – coronary heart disease, stroke, respiratory diseases (primarily pneumonia), and digestive system diseases (including liver cirrhosis) [10]. The cancer dose–response is usually assumed to be linear without a threshold (the so-called linear no-threshold or LNT assumption); this has recently received new consensus scientific support in BEIR VII and has been corroborated in another recent study [31]. It is important to note, however, that low-dose studies may not definitively prove linearity [32], and analyses of the A-bomb survivor cancer incidence dose–response using nonparametric methods suggest the possibility of nonlinearity at low doses [6].

Developmental (teratogenic) effects at higher doses have been noted in A-bomb survivors exposed *in utero* [33]; increased cancer rates have also been noted, but data are unavailable for the first 5 years after the bombings and the stronger evidence for solid cancer as well as leukemia after prenatal exposure is provided by studies of medical irradiation [3].

Genetic effects of radiation have been notorious since the *Drosophila* experiments of Müller in the 1920s and have been well characterized in animals, but the existence of discernible effects in exposed human populations has remained controversial (e.g., the issue of purported increases in rates of childhood cancer (particularly leukemia) in regions of the U.K. proximal to nuclear installations [34]). Estimates of genetic doubling dose have been promulgated based mostly on animal studies, but there is as yet no firm evidence in humans. BEIR VII uses a combination of animal-based doubling dose estimates and human data on spontaneous mutation rates to calculate estimates of radiation-induced excess rates of genetic diseases in humans, which are compatible with the lack of statistically significant excess rates observed to date in, e.g., the children of A-bomb survivors [3]. Studies in children of A-bomb survivors have progressed over several decades from studies of early,

Table 1 Sample of radiation risk estimates (Committee to Assess Health Risks from Exposure to Low Levels of Ionizing Radiation)^(a)

Outcome	Excess relative risk per gray (95% CI ^(b))	Study population
Thyroid cancer	0.53 (0.14, 2.0) (males) 1.05 (0.28, 3.9) (females) (risk primarily in persons exposed under the age of 20)	Pooled analyses
Female breast cancer	0.51 (0.28, 0.83) highest in women diagnosed under the age of 35	Pooled analysis
All solid cancer mortality except thyroid and nonmelanoma skin	0.35 (0.22, 0.55) sex-averaged, for exposure at ages between 30 and 45; declining with attained age	A-bomb survivors
Leukemia mortality	1.1 (0.1, 2.6) (males) 1.2 (0.1, 2.9) (females) (linear term, with significantly positive quadratic term), declining with age at exposure and time since exposure	A-bomb survivors
Mortality from causes other than cancer/neoplasia	0.14 (0.09, 0.19) (insufficient data to get good estimates of effect modification)	A-bomb survivors

easily observable effects such as perinatal deaths and malformations to studies of complex, multifactorial diseases expressed in middle age and older age; the latter are ongoing and results are expected to be forthcoming soon.

Studies based on doses received in medical practice, which almost always involve much larger dose to a limited part of the body than the remainder, have contributed information mostly from therapy, particularly on second primary cancers following radiation treatment of a first cancer. Diagnostic procedures, with a few notable exceptions, have resulted in cumulative doses too low to be informative [3]. Studies of occupationally exposed cohorts, particularly nuclear industry workers, have contributed important information, including a large new multinational study [31]. Owing to the lack of power of many studies, a number of analyses have been conducted on pooled data (e.g., [35, 36]). A sample of radiation risk estimates is shown in Table 1, which gives an indication of the difficulty in presenting simple summaries of risk due to complex modification by age, time, and gender.

Risk in Credit Granting and Lending Decisions: Credit Scoring

When deciding whether to lend money to a friend, relative, or colleague at work, one is not usually concerned about making a precise estimate of the probability that the loan will be repaid. This is because you know the individuals and something about them. Therefore, the decision can be perceived as a simple one that is based on your prior knowledge of the person's character, intent, and ability to repay the debt. You use what you know about their personality and past behavior to make what may be termed a *qualitative decision* where you weigh the social damage that will be done to the relationship if you do not lend the money against the financial loss that you will experience should the loan not be repaid.

Now let us consider the case of a credit granting organization, which must decide whether or not to grant credit to an individual who has applied for a loan. The general principle is the same. The credit provider must infer something about the individual's ability and intent to repay the debt. In the credit scoring literature and jargon, a customer that meets his/her credit obligations is referred to as a *good* customer; otherwise he/she is a *bad* customer. Lenders must also consider the likely return that they will make from a good customer who repays the loan against the expected loss from a bad customer who defaults. However, in a modern setting, most credit granting institutions deal with hundreds of thousands or even millions of individuals seeking credit every year. Therefore, it is not practical or cost-effective for an organization to develop the same type of in-depth relationship with their customers as can exist between two individuals who know each other well. Consequently, credit granting institutions have to rely heavily on the use of predictive models of consumer behavior to produce quantitative estimates of the likelihood of individuals defaulting on any credit that they are granted.

The techniques and methodologies used to develop and apply models of consumer repayment behavior are generally referred to as *credit scoring*. A credit scoring model can, therefore, be defined as any

quantitative predictive model that generates an estimate of the likelihood that a credit obligation will be met. Within the credit industry, the term *credit score* is usually used to describe the estimate generated by a credit scoring model for a given individual. A credit score can, therefore, be interpreted as the probability that a given individual will repay the credit applied for, should request for credit be granted. As we shall see in later sections, the most popular mathematical and statistical techniques used to construct credit scoring models, such as logistic regression, are widely used within many different areas of applied statistics and data mining. However, what differentiates credit scoring from other applications of such techniques are the objectives of the financial institutions that employ it, the nature of the data employed, and the social, ethical, and legal issues that constrain its use within the decision making process.

In this paper, our objective is to present an overview of how credit scoring is applied within the context of credit risk assessment and credit management. We focus our attention on retail sector lending for consumers: credit cards, mortgages, and instalment lending. We will particularly look at how lenders use various types of information to build predictive models of the risk of default. The remainder of this paper is organized as follows. In the next section, we explain how lenders approach the problem of modeling the risk of defaulting. We provide the context of the problem of credit scoring and explore the main approaches to developing credit scoring models, which are used to estimate the risk of default. In the section titled "Research Issues" of the paper, we present some interesting research issues that the authors feel will continue to burgeon. In the last section of the paper we offer our concluding remarks.

Consumer Credit Modeling

Introduction and the Context

Credit scoring is usually divided into application scoring and behavioral scoring. Application scoring is concerned with the decision of whether to grant credit to an individual. Behavioral scoring is concerned with the "management" of the consumer, who has been granted credit. Typical actions that the lender will take in behavioral scoring include increasing or decreasing the credit limit, or to make

better offers to consumers to reduce the probability of attrition. In this paper, we will concentrate on the estimation of the risk of default in the context of application scoring, i.e., the likelihood of an individual displaying “good” or “bad” repayment behavior. In practice, every lender has its own definition of good/bad/indeterminate customers owing to differing heads, operational, and accounting procedures, as well as the subjective views of individual credit managers as to what constitutes a good or bad customer. However, as Lewis [1] describes, most definitions of good/bad/indeterminate customers are along the following lines:

- *Good*: A customer who has maintained repayments in line with the terms of the credit agreement.
- *Bad*: A customer with a history of serious arrears, where serious is usually defined as *3 months or more behind with the repayments*. Three months is usually chosen because customers who are this far in arrears nearly always go further into arrears, resulting in a loss for the lender. Even if the customer subsequently pays the arrears, the additional cost to the lender for dealing with such an account will often mean that it will not be a profitable relationship in the long run.
- *Indeterminate*: All other cases.

The indeterminate category defines cases where good/bad performance is, for whatever reason, ambiguous for – example, a personal loan that did not go to term because the borrower repaid the loan early, or where the customer has missed the odd payment, but has not been seriously in arrears. Indeterminate categories are not usually included within the model development process [2] and therefore the problem is normally reduced to one of binary classification.

Before the development and use of credit scoring, the majority of lending decisions were made judgmentally by trained underwriters. This would typically involve a face-to-face meeting where the lender would have to judge the creditworthiness of the applicant. Decisions were made on the basis of what is known as the 5Cs of lending decisions: Capital, Collateral, Capacity, Character, and Conditions [3, 4]. First is capital, which is the amount to be borrowed, second is collateral, which are any assets which can be used as security for the debt, third is capacity which is the ability of the borrower to maintain their repayments, fourth is character, which is

the applicant’s intent to repay the debt and finally we have the conditions such as the current economic climate and forecasts. There are three main problems with the judgmental approach. First, it is time consuming and therefore expensive. Second, it is subjective, i.e., two different underwriters may make different decisions about the same loan application. Third, it is subject to prejudice; individuals from some sections of the society may be declined credit for reasons other than their likelihood of repaying the loan.

In order to make credit scoring based decisions, lenders will need analytical predictive models (*see Credit Risk Models*) to estimate the risk of default. There is still a need to collect information to infer the risk of default. In the strict empirical philosophy of building good analytical models, if any variable is likely to provide some useful information on the creditworthiness of applicants it should be used to assess the risk. However, it is possible that there are some constraints on the type of information that can be used for credit scoring. In the United Kingdom and the United States, for example, lenders are prohibited from using gender or race in their analytical models to credit score consumers. Other countries may impose other country-specific rules and regulations on the use of information for credit scoring. If a consumer applies for credit, the applicant is usually asked to complete an application form providing details about themselves that are believed to be predictive of the risk default – for example, their age, residential status, marital status, employment status, nationality, etc. The application form data is not the only piece of information that is used to infer the risk of default. The application form information does not tell us anything about the applicant’s previous credit record; i.e., whether he or she was a “good or bad” customer with other credit providers in the past. Lenders will therefore obtain this type of information from a credit reference agency, which acts as a data exchange database resource for lenders allowing them to share data about the behavior of credit applicants.

Analytical Models for Credit Scoring

In the discussion above, we have briefly discussed how lenders use different types and levels of information to estimate the risk of default on a nonjudgmental basis. Lenders, like all empirical modelers, are always looking for better models to reduce

the cost of misclassifying bad customers as good and *vice versa*. It has to be noted that what may seem to be a very small improvement in the performance of the models in statistical terms may effectively represent a huge improvement in revenue generated from these decisions. It is, therefore, not surprising that literally dozens of modeling approaches have been studied in order to find ones that yield the best efficient coefficients for modeling credit risk. In the discussion that follows, we review some of the models that are commonly described in the literature and/or used by lenders to discriminate between good and bad applicants for credit. It is impossible for us to provide a full review of all the modeling approaches. The pedagogical objective of the discussion here is to give an insight into how the most popular models are used in practice to estimate the risk of default. The models described below are logistic regression model (*see Logistic Regression*), decision trees (*see Decision Trees*), and neural networks. Readers and those who wish to pursue research in this area will find the following references useful for a more comprehensive review of the models used in credit scoring: Thomas [3] and Thomas *et al.* [5, 6].

In credit scoring, the risk of default, PD (the probability of default thereafter) is assumed to be a function of an applicant's characteristics (e.g., age, employment status, and residential status), which we define by the vector $\mathbf{X}$, $\mathbf{X} = \{X_1, X_2, X_3, \dots, X_n\}$, and unobservable or unaccountable factors, which we denote by ε :

$$PD = f(\mathbf{X}, \varepsilon) \quad (1)$$

It is to be noted that one could also model the risk of nondefaulting (1-PD). The most popular model used in credit scoring, both in academia and by lenders, is the logistic regression model [6]. The logistic model and the probability of default is formulated as follows:

$$PD = \frac{\exp(X\beta_p)}{\exp(X\beta_{NPD}) + \exp(X\beta_p)} \quad (2)$$

$\exp(X\beta_p)$ is the exponential combined effect of defaulting where $\mathbf{X}$ is the vector of characteristics as defined previously and β_p is the parameter vector defining each of the parameters for each variable used in the model. $\exp(X\beta_{NPD})$ is the exponential combined effect of nondefaulting where $\mathbf{X}$ is the vector of characteristics and β_{NPD} is the parameter vector. The

formulation of the model ensures, unlike the linear regression model, that the probability of default lies between 0 and 1. One can also transform the above logistic formulation such that the Log of the odds ratio is now a linear function of the characteristics and this is represented in equation (3). The coefficient for any variable indicates whether the log odds ratio of defaulting increases or decreases for a unit increase in that variable. In order to predict whether a customer is likely to default in the future, the applicant's characteristics information is "fed into" the estimated logistic model and resulting predicted probabilities of defaulting and not defaulting indicate the risk that will be taken if the loan or credit is granted. On the basis of the predictions of the probability model alone, the loan or credit is likely to be granted if the probability of not defaulting is less than the probability of defaulting, i.e., a good risk to take on.

$$\text{Log} \left(\frac{PD}{NPD} \right) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_n X_n \quad (3)$$

In decision trees (also commonly referred to as *classification trees*) recursive partitioning algorithms are applied where categorical splits are made recursively within the population to produce smaller and smaller homogeneous groups. Each subsidiary group (also referred to as the *child node*) contains a "purer" set of observations than its parent, containing an increasing proportion of one of the two classes of interest: that is "good" or "bad". The segmentation process is halted only when a given set of stopping criteria are met, such as the node is $>x\%$ pure (discrimination between good and bad risks) or the number of observations in the node is less than a specified minimum. The segmentation process is usually captured in the form of a *classification tree* as shown in Figure 1.

The rules for creating each branch of the tree are determined by examining the domain of all further potential splits and choosing the split that maximizes the discrimination between the two resulting groups. To illustrate, the results from decision tree above indicate that applicants who are 35 or older are four times less likely to default than others (ratio of good/bad in each node). Other rules on "what type" of applicants to grant credit, based on their characteristics, can be derived from classification trees and such rules will be employed by the decision

Figure 1 Example of a classification tree

maker to make a decision as to whether to grant or refuse credit. There are a number of possible algorithms available to find the different segments or nodes of a tree and some of them can be found in [5].

Neural network models are based on artificial intelligence methods for structuring and solving problems of classification and prediction and they are now being widely applied for data mining related problems such as customer relationship management. The process of modeling is supposed to reflect the activity process of the brain in the same manner that the “human brain” solves problems. The output results from neural network models are not as intuitive explaining why such type of modeling is less popular with lenders. While in regression terminology we

refer to variables and coefficients, in neural network models these are referred to as *inputs and weights*, respectively. The classification outcome from a neural network model is referred to as the *output*. Neural network models are less restrictive compared to the statistical underpinnings of the regression type modeling for classification. The simplest form of neural network is the single layer model illustrated in Figure 2 and the more complex but more flexible model is the multilayer formulation illustrated in Figure 3. In both figures, F stands for the transformation functions, which the analyst uses to transform the combined effect of the inputs. The multilayer formulation allows for the various interactions of independent variables or inputs described by the vector $\mathbf{X} = \{X_1, X_2, X_3, \dots, X_n\}$.

Evaluating Model Performance

The primary use of credit scoring models is as a predictive tool, to estimate the likelihood of individuals being good or bad prospects when they apply for credit. It is also true that users of credit scoring tend to deal with large populations and the point estimates for individual cases may not be of importance. Therefore, users are not overly interested in common measures of model fit, such as the R^2 coefficient for discriminant analysis (see **Credit Scoring via Altman Z-Score**) or the likelihood ratio in logistic regression; nor are lenders particularly interested in confidence intervals for the parameter estimates or individual point estimates. Instead, what is of most importance are the misclassification properties of the scoring model at specific points in the distribution of the model scores or the discriminatory power of the model, as measured across the range of model scores. It is generally recommended that the analyst use only a proportion of the data (the training sample) to estimate the model, and use the remaining proportion (the holdout sample) to assess model performance.

It is important to note here that the holdout sample is not used in the estimation of the model, and this, in a way, replicates the credit scoring process where one would feed information on new applicants into the model to assess whether they should be granted credit. The following measures of model performance tend to be of interest:

- The misclassification rate/cost within the highest scoring $x\%$ of the population, that is, the number/cost of bad scoring $\geq c$, and number/cost of good scoring $< c$ where c is the cutoff score at or above which $x\%$ of the population score.
- The misclassification rate/cost for the cutoff defined by the good/bad odds at score. For example, the number of bad risks accepted for a cutoff score where the good/bad odds are in the ratio of 10 : 1. This measure can only be calculated precisely if the output of the model can be directly interpreted as a probability of class membership.
- The overall discrimination of the model, that is, some measure of the separation between the groups of interest that the resulting scorecard provides. In this case, one can use a cross tabulation of the actual and predicted classifications of good and bad risks of the model. The error rate of the model will be defined by the number of misclassified cases (bad as good and *vice versa*) divided by the total number of cases.

A comprehensive discussion of the assessment methods that are used by credit modelers can be found in [2, 5].

A final point to note here is that predictive ability is not the only criteria by which credit scoring models are assessed. There is often a requirement for the model to be easily explicable and for the coefficients to display sensible patterns in line with the expert's opinion and univariate analysis. This is primarily owing to legislation found in many countries that requires lenders to explain why a model allocates certain scores to certain individuals. This, therefore, is perhaps most easily achieved where the model structure that is employed is in the form of either decision trees – comprising simple binary segmentation – or models that are represented by linear combination of parameter coefficients, such as with linear and logistic regression. Therefore, it is possible that when a practitioner is faced with two competing models and if the performance of each

model is very similar, the model with the simplest parameter structure will usually be chosen.

Research Issues

There are many interesting research issues and areas in credit scoring far more than can be discussed in such a short paper. Four main areas of research are summarized below. We believe that such areas of research will continue to flourish and may also represent further avenues of research.

The first is research into better classification methodologies. This primarily involves evaluating the performance classification and regression techniques that have not been previously applied to credit scoring. However, there is also growing interest into how better models can be developed by including new sources of data and choosing the most appropriate way to format the data before it is fed into the chosen model [7]. Classifier combination (ensemble modeling) has also demonstrated potential, where two or more credit scoring models are developed using different techniques and/or different data samples. The output of each model is then combined in some way to yield a single decision that may be more accurate than that produced by individual models. For a fuller discussion of classifier combination strategies refer to [8–10] *inter alia*.

A second avenue of research is into using information on consumer behavior. Information on consumer behavior such as spending patterns and lifestyle can be used into the modeling of credit risk and determining the amount and price of credit [5], for example, by overlaying the decision to lend on the basis of risk of default using measures of affordability, mailing response, attrition to a rival product, fraud, etc.

A third avenue of research is into reformulating the objectives of credit scoring. Identifying good and bad credit risks is, after all, a crude approximation to the “true” goal of segmenting customers on the basis of their contribution to profit for the lending organization. Therefore, there is increasing interest in ways in which customer profitability can be modeled. See [5, 11] for discussion on the issues surrounding profitability modeling and lending decisions.

A fourth growing area of research is on the application of predictive approaches used in consumer

credit scoring to evaluate the risk of default of companies [12, 13]. Banks and other financial institutions that grant loans or offer other credit facilities use information such as financial reports or other operations related information on organizations to assess the risk of default of companies. Moody’s rating (<http://www.moody.com>) is the best known example of the use of credit scoring predictive techniques to assess the risk of default and financial “health” of companies (*see Credit Scoring via Altman Z-Score; Decision Analysis; Utility Function*).

Conclusions

The modeling of risk will become increasingly important for lenders with the coming into effect of the Basel II accord as laid out by the Bank of International Settlements. Under this accord, lenders will need to demonstrate that the amount of capital they have is in line with what is commonly referred to as their *risk exposure*, that is, the overall portfolio risk of the various loans and credit they have granted. In this paper, we have introduced the readers to the basic principles of credit scoring. Credit scoring is the application of predictive approaches in support of lending decisions made on the estimated risk of loan default. We have discussed both the modeling approaches to credit scoring and the environmental conditions within which credit scoring is applied by practitioners. We hope that we have demonstrated the peculiarities of credit scoring within the wider disciplines of data mining, statistical modeling, and risk analysis, respectively.

Risk Management of Construction Defects

Disputes concerning alleged defects have been a common element in construction projects for many years. Attempts to manage the risks associated with such defects are properly focused on preventing the occurrence of defects and minimizing their costs when they do occur. Advice on prevention includes the use of quality materials and workmanship, as well as attending to proper maintenance after construction. The impact of a defect, if and when it occurs, may be minimized by ensuring that both developer and owner understand their respective rights and responsibilities, maintain open lines of communication, and take good faith actions to build trust with the other party.

In resolving construction disputes, including those involving alleged defects, the parties have various resolution options: negotiation, use of a project neutral, mediation, dispute review boards (DRBs), administrative board, mini-trial, binding arbitration, or litigation. As illustrated in Figure 1, the cost of resolving a dispute, the degree of control over the outcome retained by the parties involved, and the level of hostility between them will vary depending on the option used. Anecdotal evidence suggests that dispute resolution techniques through which the parties in disagreement retain control of the dispute incur fewer costs during the resolution process and keep hostilities to a minimum [1]. However, several factors, including the amount of damages being sought, influence the likelihood that a relatively inexpensive option (e.g., negotiation) will be used instead of a more expensive option (e.g., litigation).

Risk management has often been defined as a process involving three steps: hazard identification, risk assessment, and risk mitigation/communication. In the context of construction defects, as in other applications, the value of quantitative risk assessment – and, consequently, the likelihood that such an assessment will be undertaken – typically increases with the magnitude of the dispute. An assessment of construction defect risk involves estimating both the number of defects and the unit costs of addressing them. Statistical sampling and estimation are well suited to play critical roles in conducting such an assessment, particularly in estimating the prevalence of defects.

Estimation of Defect Prevalence

The use of statistical methods of inference in assessing risks associated with construction defects requires defining a population of interest and collecting information about that population by various means, including inspection and testing on a sample basis. In disputes involving a single residence or commercial building, the population of interest could refer to all work performed at the site by one or more specific contractors or subcontractors. For condominium projects or large developments of single-family homes, the population would typically comprise all housing units involved in the dispute.

If the existence of an alleged defect is in question, then an initial investigation may be undertaken for the purpose of discovery and confirmation of the defect. Often, visual inspections will be made, and some destructive testing may be performed. Attention will focus on the structures and locations on each structure showing the most evidence of distress compatible with the alleged defect. Inspection and test data collected in this way for the purpose of demonstrating the existence of an alleged defect do not provide a valid basis for extrapolating to unexamined units of the population. Instead, valid extrapolation requires scientific sampling designed and implemented according to statistical principles and best practices.

The sampling approach that is used to collect information about the population may vary depending on whether the alleged defect concerns the architectural design, building materials, methods of construction, or workmanship associated with the project in dispute. For disputes involving design, materials, or methods, the chief purpose of sampling may be to verify that the structure(s) has been built as designed, using the specified construction materials and methods. In cases where the alleged defect is expected to be present in all units, a relatively small sample can provide the confirmation. From a random sample of five units, all of which are found to possess an allegedly defective characteristic, one can conclude with greater than 95% statistical confidence that a majority of units in the population possesses that characteristic. Such a statement may be regarded as addressing the legal standard of a preponderance of evidence in that, at the prescribed level of confidence,

Figure 1 Characteristics of alternative methods for dispute resolution

a randomly selected unit more likely than not would possess the allegedly defective characteristic.

For disputes involving workmanship, the occurrence of a defect may be regarded and modeled as essentially a random event. Statistical sampling and estimation are then employed to address the task of estimating the prevalence of the defect in the population. In this setting, a defensible sampling plan must satisfy three key criteria: (a) suitability of the sampling design, (b) adequacy of the sample size, and (c) accounting for potential selection biases.

Sampling Designs

Any sample drawn for the purpose of estimating prevalence or any other characteristic of a population must be selected so that the sampled units may be regarded as being representative of the larger population. For that reason, sampling should always be done using a random mechanism to select units for inspection and/or testing. Strictly speaking, a random sample is one whose every unit of the population has a known probability of being included in the sample. Technical experts sometimes feel they can select a representative sample by exercising their professional judgment in choosing units from the population. Such an approach was discredited in statistical studies more than 70 years ago [2]. A judgment or “purposive” sample is vulnerable to the charge that a conscious or unconscious bias had influenced the selection of units. Also, statistically derived estimates from such a sample are technically invalid, because the theory on which such estimates are based includes an

assumption of random sampling from the population of interest.

The most basic form of random sampling is simple random sampling, in which every unit of the population has an equal chance of being selected for the sample. In the context of construction defects, one common objection to simple random sampling is that units of the population possessing key characteristics might be underrepresented – if not overlooked entirely – in a random probability sample. For example, in a large development of single-family homes, there may be variations in floor plans and in the time phases and parties involved in construction. Suppose that a population can be divided into subpopulations that are expected to be more homogeneous regarding the presence or absence of an alleged defect. Then, stratified random sampling can be implemented by which random samples are drawn from each subpopulation rather than from the population as a whole. Alternatively, if the sample size is sufficiently large, then one can reasonably expect that particular subsets of the population will be represented in the sample in approximate proportion to their numbers.

Sample Size

Determining the sample size – i.e., the number of units in the population to be inspected and/or tested – needed to estimate prevalence most commonly involves specifying the desired level of accuracy as well as the probability of achieving that level. The term *margin of error* is most frequently associated with a confidence level of 95%, but such values as 99, 90, and even 80% are sometimes used

Table 1 Required sample size by population size and margin of absolute error

Margin of error (%)	Number of units in population			
	100	250	500	1000
3	92	203	341	517
5	80	152	218	278
10	50	70	81	88
20	20	22	23	24

instead. An estimated prevalence of 25% with a three-percentage-point margin of error means that, with 95% confidence, the percentage of defective units in the population is between 22 and 28.

A common misconception in the construction industry, as well as in the general public, is that a fixed percentage of units in the population (e.g., 10%) must be sampled to obtain reliable results. Instead, the sample size will depend on the prescribed level of accuracy and the number of units in the population [3]. Table 1 lists the sample sizes required from populations of varying sizes to obtain estimates that achieve varying margins of error (assuming 95% confidence). Note that a higher percentage of units must be sampled from smaller populations to achieve the same margin of error as in larger populations. The absolute number, rather than the percentage, of sampled units determines the accuracy of resulting estimates of prevalence.

Selection Bias and Substitution

Although the number of units to be sampled is typically determined to control the magnitude of sampling error in resulting estimates, attention must also be given to sources of nonsampling error. In assessing the prevalence of defects, particularly in residential construction, sample-based estimates may be especially vulnerable to bias from nonresponding households. Suppose, for example, that determination of whether an alleged defect is present in a housing unit requires not only visual inspection but some degree of destructive testing also. If the owner of the housing unit sees no evidence of damage and believes the unit is unlikely to possess the alleged defect, he or she may be less willing to cooperate and grant access if the unit is selected for inclusion in the sample. Consequently, the data from responding households

may overestimate the prevalence of the defect in the population.

Selection bias can be exacerbated when alternates are substituted for originally selected housing units that are not available for measurement. However, substitution does provide gains in precision and, by restoring the original sample size, yields estimates that possess the prescribed margin of sampling error. There appears to be no clear theoretical or empirical evidence to accept or reject the practice of substitution [4]. If the percentage of nonresponding sampled units is small, the difference between estimates with and without substitution is likely to be negligible.

Regardless of whether substitution is used or not, the potential for nonresponse bias in sampling can be monitored by listing nonresponding units and documenting the reasons for their unavailability. In some cases, it may be possible to estimate and adjust for selection bias. If data on one or more characteristics associated with the occurrence of the alleged defect are available for both nonresponding and responding units, then a formal statistical test can be conducted to determine whether the two groups of units differ significantly with respect to the measured characteristic. If differences exist, then estimates of prevalence for nonresponding units can be obtained on the basis of the empirical link between values of the measured characteristic and occurrence of the alleged defect. Alternatively, prevalence limits based on bounding assumptions may be calculated to assess the sensitivity of estimates to possible sources of bias.

Other Statistical Considerations

In disputes concerning alleged construction defects, the involved parties will typically be interested in establishing whether there is a physical link between an alleged defect and observed damage. Because the data gathered from inspections and testing of sampled units are observational in nature – and not the result of controlled experimentation – proper interpretation of these data requires consideration of whether other so-called “confounding” factors might be present. For example, moisture intrusion might be attributed to improper window installation but could also be caused by poor roof sheathing. Inspections and tests should be designed and executed to generate information that enables evaluation of alternative explanations for any observed association between occurrence of an alleged defect and property damage.

Inspection and test data can thus provide a basis for judging the empirical evidence for damage theories advocated in a construction dispute. For example, consider the allegation that improper soil compaction has caused tilting and cracking of foundation slabs. This allegation can be examined by measuring the strength of association between foundation tilt (as determined from manometer surveys) and variables such as soil density and depth of fill. Standard statistical methods, including regression and analysis of variance, can be applied in drawing conclusions from formal comparisons.

The findings from inferential statistical methods depend on one or more assumptions (which may or may not be explicitly stated) concerning the process by which the data were generated. The validity of these assumptions should be checked using the data and all other relevant and available information. In circumstances when data are sparse, more than one statistical model may provide an acceptable fit. Attention should be given to determining the robustness of conclusions – that is, the extent to which final answers differ when plausible alternative statistical models are used.

Cost of Repair

Completion of a formal quantitative risk assessment requires integrating sample-based estimates of defect prevalence with expert judgments concerning the unit cost of addressing the observed defects. At this stage, particularly in litigious disputes, construction experts retained by the opposing parties may produce substantially different estimates of unit repair costs. These differences can usually be traced to divergent opinions concerning whether a minor repair will suffice or a major replacement is indicated.

The Construction Defect Risk Manager

Possessing information concerning both the prevalence of defects and their estimated unit costs, the risk manager is then equipped to weigh the options and pursue a course of action that is compatible with his or her client's risk/reward profile. Information about the costs of alternative methods of dispute resolution, as well as their likelihoods of success, can also be considered at this point in the evaluation. The risk manager may choose to apply Bayesian methods for subjective probability assessment (*see Bayesian Statistics in Quantitative Risk Assessment*) and *decision analysis* (*see Decision Analysis*) as formal tools to assist in this process.

Risk Measures and Economic Capital for (Re)insurers

Risk Measurement and Capital

A *risk measure* is a function that assigns real numbers to random variables representing uncertain payoffs, e.g., insurance losses. The interpretation of the outcome of a risk measure depends on the context in which it is used. Historically, there have been three main areas of application of risk measures:

- as representations of risk aversion in asset pricing models, with a leading paradigm being the use of the variance as a risk measure in Markowitz portfolio theory [1];
- as tools for the calculation of the insurance price corresponding to a risk – under this interpretation, risk measures are called *premium calculation principles* (see **Premium Calculation and Insurance Pricing**) in the classic actuarial literature, e.g., [2];
- as quantifiers of the economic capital that the holder of a particular portfolio or risks should safely invest in, e.g., [3].

This article is mainly concerned with the last-mentioned interpretation of risk measures.

The *economic* or *risk capital* (see **Solvency**) held by a (re)insurer corresponds to the level of safely invested assets used to protect itself against unexpected volatility of its portfolio's outcome. One has to distinguish economic capital from regulatory capital, which is the minimum required economic capital level as set by the regulator. In fact, much of the impetus for the use of risk measures in the quantification of capital requirements comes from the area of regulating financial institutions. Banking supervision [4] and, increasingly, insurance regulation [5] have been promoting the development of companies' *internal models* for modeling risk exposures. In this context, the application of a risk measure (most prominently *value-at-risk* (see **Value at Risk (VaR) and Risk Measures**)) on the modeled aggregate risk profile of the insurance company is required.

Economic capital generally exceeds the minimum set by the regulator. Subject to this constraint, economic capital is determined so as to maximize performance metrics for the insurance company, such as total shareholder return [6]. Such maximization takes into account two conflicting effects of economic capital [7]:

- An insurance company's holding economic capital incurs costs for its shareholders that can be opportunity or frictional costs.
- Economic capital reduces the probability of default of the company as well as the severity of such default on its policyholders. This enables the insurance company to obtain a better rating of its financial strength, and thereby attract more insurance business at higher prices.

Calculation of the optimal level of economic capital using such arguments is quite complicated and depends on factors that are not always easy to quantify, such as frictional capital costs, and on further constraints, such as the ability of an insurance company to raise capital in a particular economic and regulatory environment.

We could, however, consider that there is a particular calibration of the (regulatory or other) risk measure, which gives for the insurance company's exposure, a level of economic capital that coincides with that actually held by the company. In that sense, risk measures can be used to interpret exogenously given economic capital amounts. Such interpretation can be in the context of capital being set to achieve a target rating, often associated with a particular probability of default. Discussion of economic capital in the context of risk measures should therefore be caveated as being *ex post*.

Finally, we note that the level of economic capital calculated by a risk measure may be a notional amount, as the company will generally not invest all its surplus in risk-free assets. This can be dealt with by absorbing the volatility of asset returns in the risk capital calculation itself.

Definition and Examples of Risk Measures

We consider a set of risks $\mathcal{X}$ that the insurance company can be exposed to. The elements $X \in \mathcal{X}$ are random variables, representing losses at a fixed time

horizon T (see **Risk Classification/Life; Risk Classification in Nonlife Insurance**). If under a particular state of the world ω , the variable $X(\omega) > 0$, then we consider this to be a loss, while negative outcomes will be considered as gains. For convenience, it is assumed throughout that the return from risk-free investment is 1 or, alternatively, that all losses in $\mathcal{X}$ are discounted at the risk-free rate. A risk measure ρ is then defined as a functional

$$\rho : \mathcal{X} \mapsto \mathbb{R} \quad (1)$$

If X corresponds to the aggregate net risk exposure of an insurance company (i.e., the difference between liabilities and assets, excluding economic capital), and the economic capital corresponds to $\rho(X)$, then we assume that the company defaults when $X > \rho(X)$.

In the terminology of [3] (and subject to some simplification), a risky position X is called *acceptable* if $\rho(X) < 0$, implying that some capital may be released without endangering the security of the holder of X , while $\rho(X) \geq 0$ means that X is a nonacceptable position and that some capital has to be added to it.

Some examples of simple risk measures proposed in the actuarial and financial literature (e.g., [8, 9]) are given below.

Example 1: Expected value principle

$$\rho(X) = \lambda E[X], \quad \lambda \geq 1 \quad (2)$$

Besides its application in insurance pricing, where it represents a proportional loading, this risk measure, in essence, underlies simple regulatory minimum requirements, such as the current EU Solvency rules, which determine capital as a proportion of an exposure measure, such as premium.

Example 2: Standard deviation principle

$$\rho(X) = E[X] + \kappa \sigma[X], \quad \kappa \geq 0 \quad (3)$$

In this case, the loading is risk sensitive, as it is a proportion of the standard deviation. This risk measure is encountered in reinsurance pricing (see **Reinsurance**), while also relating to Markowitz portfolio theory. In the context of economic capital, it is usually derived as an approximation to other risk

measures, with this approximation being accurate for the special case of multivariate normal (more generally elliptical) distributions [10].

Example 3: Exponential premium principle

$$\rho(X) = \frac{1}{a} \ln E[e^{aX}], \quad a > 0 \quad (4)$$

The exponential premium principle is a very popular risk measure in the actuarial literature, e.g., [11]. Part of the popularity stems from the fact that, in the classic ruin problem (see **Ruin Theory**), it gives the required level of premium associated with Kramer–Lundberg bounds for ruin probabilities. We note that this risk measure has been recently considered in the finance literature under the name *entropic risk measure* [12].

Example 4: Value-at-risk

$$\rho(X) = \text{VaR}_p(X) = F_X^{-1}(p), \quad p \in (0, 1) \quad (5)$$

where F_X is the cumulative probability distribution of X and F_X^{-1} is its (pseudo)inverse. $\text{VaR}_p(X)$ is easily interpreted as the amount of capital that, when added to the risk X , limits the probability of default to $1 - p$. Partly because of its intuitive attractiveness, value-at-risk has become the risk measure of choice for both banking and insurance regulators. For example, the UK regulatory regime for insurers uses $\text{VaR}_{0.995}(X)$ [13], while a similar risk measure has been proposed in the context of the new EU-wide Solvency II regime [5].

Example 5: Expected shortfall

$$\rho(X) = \text{ES}_p(X) = \int_p^1 F_X^{-1}(q) \, dq, \quad p \in (0, 1) \quad (6)$$

This risk measure, also known as *tail-(or conditional-)value-at-risk*, corresponds to the average of all VaR_p 's above the threshold p . Hence, it reflects both the probability and the severity of a potential default. Expected shortfall has been proposed in the literature as a risk measure correcting some of the theoretical weaknesses of value-at-risk [14]. Subject to continuity of F_X at the threshold VaR_p , expected shortfall coincides with the *tail conditional expectation*, defined by

$$\rho(X) = E[X | X > F_X^{-1}(p)] \quad (7)$$

Example 6: Distortion risk measure

$$\rho(X) = - \int_{-\infty}^0 (1 - g(1 - F_X(x))) dx + \int_0^{\infty} g(1 - F_X(x)) dx \quad (8)$$

where $g : [0, 1] \mapsto [0, 1]$ is increasing and concave [15]. This risk measure can be viewed as an expectation under a distortion of the probability distribution effected by the function g . It can be easily shown that expected shortfall is a special case obtained by a bilinear distortion [14]. Distortion risk measures can be viewed as Choquet integrals [16, 17], which are extensively used in the economics of uncertainty, e.g., [18]. An equivalent class of risk measures defined in the finance literature are known as *spectral risk measures* [19].

Properties of Risk Measures

The literature is rich in discussions of the properties of alternative risk measures, as well as the desirability of such properties (*see Individual Risk Models*), e.g., [2, 3, 9, 20]. In view of this, the current discussion is invariably selective.

An often required property of risk measures is that of *monotonicity*, stating

$$\text{If } X \leq Y, \text{ then } \rho(X) \leq \rho(Y) \quad (9)$$

This reflects the obvious requirement that losses that are always higher should also attract a higher capital requirement.

A further appealing property is that of *translation* or *cash invariance*,

$$\rho(X + a) = \rho(X) + a, \quad \text{for } a \in \mathbb{R} \quad (10)$$

This postulates that adding a constant loss amount to a portfolio increases the required risk capital by the same amount. We note that this has the implication that

$$\rho(X - \rho(X)) = \rho(X) - \rho(X) = 0 \quad (11)$$

which, in conjunction with monotonicity, facilitates the interpretation of $\rho(X)$ as the minimum capital amount that has to be added to X to make it acceptable.

Two conceptually linked properties are the ones of *positive homogeneity*,

$$\rho(bX) = b\rho(X), \quad \text{for } b \geq 0 \quad (12)$$

and *subadditivity*,

$$\rho(X + Y) \leq \rho(X) + \rho(Y), \quad \text{for all } X, Y \in \mathcal{X} \quad (13)$$

Positive homogeneity postulates that a linear increase in the risk exposure X also implies linear increase in risk. Subadditivity requires that the merging of risks should always yield a reduction in risk capital because of diversification.

Risk measures satisfying the four properties of monotonicity, translation invariance, positive homogeneity, and subadditivity have become widely known as *coherent* [3]. This particular axiomatization, also proposed in an actuarial context [16, 21], has achieved near-canonical status in the world of financial risk management. While value-at-risk generally fails the subadditivity property, because of its disregard for the extreme tails of distributions, part of its appeal to regulators and practitioners stems from its use as an approximation to a coherent risk measure.

Nonetheless, coherent risk measures have also attracted criticism because of their insensitivity to the aggregation of large positively dependent risks implied by the latter two properties, e.g., [20]. The weaker property of *convexity* has been proposed in the literature [22], a property already discussed in [23]. Convexity requires that:

$$\rho(\lambda X + (1 - \lambda)Y) \leq \lambda\rho(X) + (1 - \lambda)\rho(Y), \quad \text{for all } X, Y \in \mathcal{X} \text{ and } \lambda \in [0, 1] \quad (14)$$

Convexity, while retaining the diversification property, relaxes the requirement that a risk measure must be insensitive to aggregation of large risks. It is noted that subadditivity is obtained by combining convexity with positive homogeneity. Risk measures satisfying convexity, and applying increasing penalties for large risks have been proposed in [24].

Risk measures produce an ordering of risks, in the sense that $\rho(X) \leq \rho(Y)$ means that X is considered less risky than Y . One would wish that ordering should conform to standard economic theory, i.e., to be consistent with widely accepted notions of stochastic order such as first- and second-order stochastic dominance and convex order; see [9, 25].

It has been shown that, under some relatively mild technical conditions, risk measures that are monotonic and convex produce such a consistent ordering of risks [26].

A further key property relates to the dependence structure between risks under which the risk measure becomes *additive*

$$\rho(X + Y) = \rho(X) + \rho(Y) \quad (15)$$

as this implies a situation where neither diversification credits nor aggregation penalties are assigned. In the context of subadditive risk measures, *comonotonic additivity* is a sensible requirement, as it postulates that no diversification is applied in the case of comonotonicity (*see Comonotonicity*) (the maximal level of dependence between risks, e.g., [27]). On the other hand, one could require a risk measure to be *independent additive*. If such a risk measure is also consistent with the stop-loss or convex order, by the results of [28], it is guaranteed to penalize any positive dependence by being superadditive (i.e., $\rho(X + Y) \geq \rho(X) + \rho(Y)$) and reward any negative dependence by being subadditive.

The risk measures defined above satisfy the following properties:

Expected value principle: monotonic, positive homogenous, additive for all dependence structures;

Standard deviation principle: translation invariant, positive homogenous, subadditive;

Exponential premium principle: monotonic, translation invariant, convex, independent additive;

Value-at-risk: monotonic, translation invariant, positive homogenous, subadditive for joint elliptically distributed risks [10], comonotonic additive;

Expected shortfall: monotonic, translation invariant, positive homogenous, subadditive, comonotonic additive;

Distortion risk measure: monotonic, translation invariant, positive homogenous, subadditive, comonotonic additive.

Finally, we note that all risk measures discussed in this contribution are *law invariant*, meaning that $\rho(X)$ only depends on the distribution function of X [21, 29]. This implies that two risks characterized by the same probability distribution would be allocated the same amount of economic capital.

Constructions and Representations of Risk Measures

Indifference Arguments

Economic theories of choice under risk seek to model the preferences of economic agents with respect to uncertain payoffs. They generally have representations in terms of *preference functionals* $V : -\mathcal{X} \mapsto \mathbb{R}$, in the sense that

$$-X \text{ is preferred to } -Y \iff V(-X) \geq V(-Y) \quad (16)$$

(Note that the minus sign is applied because we have defined risk as losses, while preference functionals are typically applied on payoffs.)

Then a risk measure can be defined by assuming that the addition to initial wealth W of a liability X and the corresponding capital amount $\rho(X)$ does not affect preferences [8] (*see Risk-Neutral Pricing: Importance and Relevance*)

$$V(W_0 - X + \rho(X)) = V(W_0) \quad (17)$$

Often in this context, $W = 0$ is assumed for simplicity.

The leading paradigm of choice under risk is the von Neumann–Morgenstern *expected utility theory* (*see Utility Function*) [30], under which

$$V(W) = E[u(W)] \quad (18)$$

where u is an increasing and concave *utility function*. A popular choice of utility function is the *exponential utility*

$$u(w) = \frac{1}{a} (1 - e^{-aw}), \quad a > 0 \quad (19)$$

It can be easily seen that equations (17), (18), and (19) yield the exponential premium principle defined in the section “Definition and Examples of Risk Measures”.

An alternative theory is the *dual theory of choice under risk* [31], under which

$$V(W) = - \int_{-\infty}^0 (1 - h(1 - F_W(w))) dw + \int_0^{\infty} h(1 - F_W(w)) dw \quad (20)$$

where $h : [0, 1] \mapsto [0, 1]$ is increasing and convex. It can then be shown that the risk measure obtained

from equations (17) and (20) is a distortion risk measure with $g(s) = 1 - h(1 - s)$. For the function

$$h(s) = 1 - (1 - s)^{\frac{1}{\gamma}}, \quad \gamma > 1 \quad (21)$$

the well-known *proportional hazards transform*, with $g(s) = s^{1/\gamma}$ is obtained [15].

More detailed discussions of risk measures resulting from alternative theories of choice under risk (see **Axiomatic Models of Perceived Risk**) and references to the associated economics literature are given in [24, 32].

It should also be noted that the construction of risk measures from economic theories of choice must not necessarily be *via* indifference arguments. If a risk measure satisfies the convexity and monotonicity properties, then by setting $U(W) = -\rho(-W)$ we obtain a monotonic concave preference functional. The translation invariance property of the risk measure then makes U also translation invariant. Hence we could consider convex risk measures as the subset of concave preference functionals that satisfy the translation invariance property (subject to a minus sign). Such preference functionals are sometimes called *monetary utility functions*, as their output can be interpreted as being in units of money rather than of an abstract notion of satisfaction.

Axiomatic Characterizations

An alternative approach to deriving risk measures is by fixing a set of properties that risk measures should satisfy and then seeking an explicit functional representation (see **Axiomatic Measures of Risk and Risk-Value Models**).

For example, coherent (i.e., monotonic, translation invariant, positive homogenous, and subadditive) risk measures can be represented by Artzner *et al.* [3]

$$\rho(X) = \sup_{\mathbb{P} \in \mathcal{P}} E_{\mathbb{P}}[X] \quad (22)$$

where $\mathcal{P}$ is a set of probability measures. By including the comonotonic additivity property, one gets the more specific structure of $\mathcal{P} = \{\mathbb{P} : \mathbb{P}(A) \leq v(A) \text{ for all sets } A\}$, where v is a submodular set function known as a (*Choquet*) *capacity* [17]. The additional property of law of invariance enables writing $v(A) = g(\mathbb{P}_0(A))$, where $\mathbb{P}_0$ is the objective probability measure and g a concave distortion function [21]. This finally yields a representation of coherent, comonotonic additive, law-invariant risk measures as distortion risk measures. An alternative

route toward this representation is given by Kusuoka [29].

The probability measures in $\mathcal{P}$ have been termed *generalized scenarios* [3] with respect to which the worst case expected loss is considered. On the other hand, representations such as equation (22) have been derived in the context of robust statistics [33] and decision theory, known as the *multiple-priors model* [34].

A related representation result for convex risk measures is derived in [22], while results for independent additive risk measures are given in [35, 36].

Reweighting Probabilities

An intuitive construction of risk measures is by reweighting the probability distribution of the underlying risk

$$\rho(X) = E[X\zeta(X)] \quad (23)$$

where ζ is generally assumed to be an increasing function with $E[\zeta(X)] = 1$ and representation (23) could be viewed as an expectation under a change of measure. Representation (23) is particularly convenient when risk measures and related functionals have to be evaluated by Monte Carlo simulation.

Many well-known risk measures can be obtained in this way. For example, making appropriate assumptions on F_X and g , one can easily show that for distortion measures it is

$$\rho(X) = E[Xg'(1 - F_X(X))] \quad (24)$$

On the other hand, the exponential principle can be written as

$$\rho(X) = E \left[X \int_0^1 \frac{e^{\gamma a X}}{E[e^{\gamma a X}]} d\gamma \right] \quad (25)$$

The latter representation is sometimes called a *mixture of Esscher principles* and studied in more generality in [35, 36].

Capital Allocation

Problem Definition

Often the requirement arises that the risk capital calculated for an insurance portfolio has to be allocated to business units. There may be several reasons for such a capital allocation exercise, the main ones being performance measurement/management and insurance pricing.

Capital allocation is not a trivial exercise, given that, in general, the risk measure used to set the aggregate capital is not additive. In other words, if one has an aggregate risk Z for the insurance company, breaking down to subportfolios $X_1, \dots, X_n$, such that

$$Z = \sum_{j=1}^n X_j \quad (26)$$

it generally is

$$\rho(Z) \neq \sum_{j=1}^n \rho(X_j) \quad (27)$$

because of diversification/aggregation issues.

The capital allocation problem then consists of finding constants $d_1, \dots, d_n$ such that

$$\sum_{j=1}^n d_j = \rho(Z) \quad (28)$$

where the allocated capital amount d_i should, in some way, reflect the risk of subportfolio X_i . Early papers in the actuarial literature that deal with cost allocation problems in insurance are [37, 38], the former taking a risk theoretical view, and the later examining alternative allocation methods from the perspective of cooperative game theory. A specific application of cooperative game theory to risk capital allocation, including a survey of the relevant literature, is [39].

Marginal Cost Approaches

Marginal cost approaches associate allocated capital to the impact that changes in the exposure to subportfolios have on the aggregate capital. Denote for vector of weights $\mathbf{w} \in [0, 1]^n$,

$$Z^{\mathbf{w}} = \sum_{j=1}^n w_j X_j \quad (29)$$

Then the marginal cost of each subportfolio is given by

$$MC(X_i; Z) = \left. \frac{\partial \rho(Z^{\mathbf{w}})}{\partial w_i} \right|_{\mathbf{w} = \mathbf{1}} \quad (30)$$

subject to appropriate differentiability assumptions. If the risk measure is positive homogenous, then by Euler's theorem we have that

$$\sum_{j=1}^n MC(X_j; Z) = \rho(Z) \quad (31)$$

and we can hence use marginal costs $d_i = MC(X_i; Z)$ directly as the capital allocation.

If the risk measure is in addition subadditive, then we have that [40]

$$d_i = MC(X_i; Z) \leq \rho(X_i) \quad (32)$$

i.e., the allocated capital amount is always lower than the stand-alone risk capital of the subportfolio. This corresponds to the game theoretical concept of the *core*, in that the allocation does not provide an incentive for splitting the aggregate portfolio. This requirement is consistent with the subadditivity property, which postulates that there is always a benefit in pooling risks.

In the case that no such strong assumptions as positive homogeneity (and subadditivity) are made with respect to the risk measure, marginal costs will, in general, not yield an appropriate allocation, as they will not add up to the aggregate risk. Cooperative game theory then provides an alternative allocation method, based on the *Aumann–Shapley value* [41], which can be viewed as a generalization of marginal costs

$$AC(X_i, Z) = \int_0^1 MC(X_i; \gamma Z) d\gamma \quad (33)$$

It can easily be seen that if we set $d_i = AC(X_i, Z)$ then the d_i s add up to $\rho(Z)$ and that for positive homogenous risk measures the Aumann–Shapley allocation reduces to marginal costs. Early applications of the Aumann–Shapley value to cost allocation problems are [42, 43].

For the examples of risk measures that were introduced in the section “Definition and Examples of Risk Measures”, the following allocations are obtained from marginal costs/Aumann–Shapley.

Example 7: Expected value principle

$$d_i = \lambda E[X_i] \quad (34)$$

Example 8: Standard deviation principle

$$d_i = E[X_i] + \kappa \frac{\text{Cov}(X_i, Z)}{\sigma[Z]} \quad (35)$$

Example 9: Exponential premium principle

$$d_i = \int_0^1 \frac{E[X_i \exp(\gamma a Z)]}{E[\exp(\gamma a Z)]} d\gamma \quad (36)$$

Example 10: Value-at-risk [44]

$$d_i = E[X_i | Z = \text{VaR}_p(Z)] \quad (37)$$

under suitable assumptions on the joint probability distribution of (X_i, Z) .

Example 11: Expected shortfall [44]

$$d_i = E[X_i | Z > \text{VaR}_p(Z)] \quad (38)$$

under suitable assumptions on the joint probability distribution of (X_i, Z) .

Example 12: Distortion risk measure [45]

$$d_i = E[X_i g'(1 - F_Z(Z))] \quad (39)$$

assuming representation (24) is valid.

Alternative Approaches

While marginal cost-based approaches are well established in the literature, there are a number of alternative approaches to capital allocation. For example, we note that marginal costs generally depend on the joint distribution of the individual subportfolio and the aggregate risk. In some cases, this dependence may not be desirable, for example, when one tries to measure the performance of subportfolios to allocate bonuses. In that case, a simple *proportional repartition of costs* [38] may be appropriate:

$$d_i = \rho(X_i) \frac{\rho(Z)}{\sum_{j=1}^n \rho(X_j)} \quad (40)$$

Different issues emerge when the capital allocation is to be used for managing the performance of the aggregate portfolio, as measured by a particular metric, such as return on capital. Assume that $\hat{X}_i$, $i = 1, \dots, n$ correspond to the liabilities from subportfolio i minus reserves corresponding to those liabilities, such that $E[\hat{X}_i] = 0$. We then have the breakdown

$$X_i = \hat{X}_i - p_i \quad (41)$$

where p_i corresponds to the underwriting profit from the insurer's subportfolio (e.g., line of business) i , such that $\sum_{j=1}^n \hat{X}_j = \hat{Z}$ and $\sum_{j=1}^n p_j = p$. Then we define the return on capital for the whole insurance portfolio by

$$RoC = \frac{p}{\rho(\hat{Z})} \quad (42)$$

This is discussed in depth in [44] for the case that ρ is a coherent risk measure. It is then considered whether assessing the performance of subportfolios by

$$RoC_i = \frac{p_i}{d_i} \quad (43)$$

where d_i represents capital allocated to $\hat{X}_i$, provides the right incentives for optimizing performance. It is shown that marginal costs is the unique allocation mechanism that satisfies this requirement as set out

in that paper. A closely related argument is that under the marginal cost allocation, a portfolio balanced to optimize aggregate return on capital has the property that $RoC = RoC_i$, for all i . While this produces a useful performance yardstick that can be used throughout the company, some care has to be taken when applying marginal cost methodologies. In particular, if the marginal capital allocation to a subportfolio is small, e.g., for reasons of diversification, the insurer should be careful not to let that fact undermine underwriting standards. A proportional allocation method could also be used for reference, to avoid that danger.

Often, one may be interested in calculating capital allocations that are, in some sense, optimal. For example, in [46] capital allocations are calculated such that a suitably defined distance function between individual subportfolios and allocated capital levels is minimized. This methodology reproduces many capital allocation methods found in the literature, while also considering the case that aggregate economic capital is exogenously given rather than calculated *via* a risk measure. A different optimization approach to capital allocation is presented in [47].

An alternative strand of the literature on capital allocation relates to the pricing of the policyholder deficit due to the insurer's potential default [48]. This is discussed in slightly greater detail in the section titled "Frictional Capital Costs and the Cost of Default".

Economic Capital and Insurance Pricing

Cost of Capital

A way of associating risk measures and economic capital with insurance prices is *via cost-of-capital* arguments. It is considered that the shareholders of an insurance company incur an opportunity cost by providing economic capital. Therefore, they also require a return on that capital that is in excess of the risk-free rate. This is typically calculated *via* equilibrium arguments, with the methodology of *weighted average cost of capital* (WACC) being the prime example [49]. It is, furthermore, assumed that the additional return on capital will be earned by including a cost-of-capital adjustment in insurance premiums.

If we denote by CoC the cost of capital associated with the insurance company, then, using the notation

of the previous section, the required profit for its insurance portfolio $Z = \hat{Z} - p$ is:

$$p = CoC \cdot \rho(\hat{Z}) \quad (44)$$

It should be apparent from the preceding discussion that cost of capital and return on capital are closely linked concepts; in fact evaluation of the former often leads to a target level for the latter.

A capital allocation $\sum_{j=1}^n d_j = \rho(\sum_{j=1}^n \hat{X}_j) = \rho(\hat{Z})$ then yields the required profit for each subportfolio:

$$p_i = CoC \cdot d_i \quad (45)$$

Frictional Capital Costs and the Cost of Default

Cost-of-capital approaches to insurance pricing have been criticized in the literature for a number of reasons, including [6]:

- The return on (or cost of) capital considered may be an inadequate measure of performance, as the total shareholder return is influenced by other factors too.
- The methodology does not explicitly allow for the potential default of the insurer. Hence, by associating a fixed cost with economic capital, the benefits of increased policyholder security are disregarded.

An alternative approach is to break down the insurance price into three parts [7]:

- the economic (market consistent) value of the insurance liability;
- the frictional cost of holding capital;
- the cost to policyholders in case of the default by the insurer.

The economic value of the liability Z , denoted here by $EV(Z)$, where EV is a linear pricing functional derived by a financial valuation method, e.g., by equilibrium or no-arbitrage arguments. The frictional costs, which may comprise double taxation, agency costs, and the costs of financial distress [7], may be written in their simplest form as a fixed percentage fc of aggregate capital, i.e., $fc \cdot \rho(Z)$.

The loss to policyholders caused by the insurer's default or *policyholder deficit* is given by

$$(Z - \rho(Z))_+ \quad (46)$$

that is, by the excess of the insurer's liabilities over its assets. It is argued by Myers and Read [48] that the economic value of this cost should be removed from the insurance premium, as it corresponds to a loss to policyholders, given the insurer's shareholders' limited liability; an expression similar to equation (46) has thus been termed the *limited liability put option* or *default option*.

The total premium for the insurer can then be calculated as

$$EV(Z) + fc \cdot \rho(Z) - EV[(Z - \rho(Z))_+] \quad (47)$$

On the basis of expression (48), and assuming ρ is a coherent risk measure, marginal costs give us the allocation of the insurance price for subportfolio X_i by

$$EV(X_i) + fc \cdot d_i - EV[(X_i - d_i)\mathbf{I}_{\{Z > \rho(Z)\}}] \quad (48)$$

where $\mathbf{I}_A$ denotes the indicator of set A .

The discussion on allocating capital by the value of the default option is, in the main, motivated by Myers and Read [48]. That paper, as well as [50] that anticipates it, adopts a slightly different approach, whereby, the aggregate capital allocated to subportfolios is exogenously given rather than calculated *via* a risk measure. Moreover, these papers are set in a dynamic framework rather than the simple 1-period one adopted in this contribution.

Incomplete Markets and Risk Measures

As discussed in the section "Risk Measurement and Capital", risk measures have been traditionally used in the insurance industry to calculate prices. The difference $\rho(X) - E[X]$ then is considered as a *safety loading*. When the risk measures are law invariant, such as those considered here, then the safety loading depends only on the distribution of X and does not reflect market conditions. Moreover, as illustrated in [51], using law-invariant risk measures as pricing functionals, e.g., to reflect market frictions, can also be problematic.

In financial economics, securities are priced using no-arbitrage arguments, which, in a complete market, result in the price of a risk equal to the cost of its replication by traded instruments. Such a market consistent approach to valuation of insurance liabilities is propagated in the context of Solvency II [5]. However, insurance markets are typically incomplete, meaning that no exact replication can be achieved by trading. This motivates approaches

where the price equals the cost of replication with some acceptable level of accuracy. Two examples of incomplete market approaches based on partial replication are mean variance [52] and quantile hedging [53].

The formulation of such pricing methods often utilizes risk measures to define the quality of replication. Different calibrations of these risk measures, corresponding to different levels of risk aversion, give rise to a range of possible prices. It can thus be argued that there is a continuum between pricing and holding risk capital in incomplete markets, with the main difference being the degree of risk aversion considered in each application. (A rather different approach to incomplete market pricing is based on indifference arguments in a dynamic setting is [54], which is closely related to the risk measures discussed in the section “Indifference Arguments.”) Hence one could consider financial pricing of insurance as being a dynamic extension of the traditional actuarial risk measures or premium principles, taking place in a richer economic environment where dynamic trading is possible.

Risk–Benefit Analysis for Environmental Applications

In a risk–benefit analysis, the issue examined is the trade-off between losses suffered from illnesses or diseases, due to exposures to an environmental contaminant, and losses due to toxic effects induced by environmental remediation, e.g., chemicals used in cleanup or disinfectants used to reduce microbial exposures (*see* **Environmental Hazard; Environmental Health Risk**). Perhaps, this process is more appropriately labeled a risk–risk analysis. An additional societal complication arises when risks and benefits are incurred by different individuals. A risk management or societal question is whether the benefits (e.g., reductions of severity or incidences of illnesses, diseases, or death) outweigh the risks introduced by interventions (e.g., by-products from disinfectants used for drinking water treatment) (*see* **Enterprise Risk Management (ERM)**). The solution depends not only on the incidences of adverse health effects, but also on their relative costs (e.g., medical expenses and/or number of workdays lost). A risk–benefit issue also arises for drugs with unwanted side effects and for vitamins and essential minerals that become toxic at high doses. The total relative cost or loss due to an adverse health effect is the incidence of the effect times its relative cost or loss. In the following section, a quantitative procedure is described for estimating the optimum dose for a chemical intervention, drug, vitamin, or essential mineral that minimizes the overall expected relative loss from the risk of illness or disease due to environmental exposure and the expected relative loss induced by chemical, drug, or dietary intervention.

Method for Optimum Dose of Intervention

Let d represent the dose of a chemical introduced to reduce the incidence of an adverse effect. Let $P_1(d)$ represent the expected probability of the adverse effect in the presence of an intervention dose of d units. For example, $P_1(d)$ might represent the probability of illness for a person exposed at d units of a chemical treatment (e.g., disinfectant, drug, vitamin, or essential mineral). It is assumed that $P_1(d)$

is a monotonically decreasing function of d , i.e., $0 < P_1(d) \leq P_1(0)$, where $P_1(0)$ is the background incidence without intervention. Let c_1 represent the expected cost (loss) due to the occurrence of the adverse effect. Loss is expressed as some appropriate metric, e.g., monetary cost of treatment of a disease, length of hospital stay, lost workdays, or life shortening. Then, the expected loss due to the adverse event is the product of the probability of the adverse event times the loss per event, $E_1(\text{loss}) = c_1 P_1(d)$, as a monotonically decreasing function of d .

Let $P_2(d)$ represent the probability of a different adverse effect (e.g., toxic effect, illness, or disease) induced by a dose, d , of an intervention agent. It is assumed that $P_2(d)$ is a monotonically increasing function of d . Note that $P_1(d)$ and $P_2(d)$ must be expressed on the same basis, e.g., probability per serving or per lifetime. Let c_2 represent the cost (loss) due to an adverse effect induced by the intervention agent, where c_2 must be expressed in the same metric as c_1 . The expected loss induced by the intervention product, $E_2 = c_2 P_2(d)$, is a monotonically increasing function d .

Chen and Gaylor [1] used the principle of minimum expected loss for setting the optimum beneficial dose of a compound accompanied by a potential toxic effect.

The total expected loss from a product treated with a dose, d , of an intervention product is

$$E(\text{loss}) = c_1 P_1(d) + c_2 P_2(d) \quad (1)$$

This results in a U-shaped curve as a function of dose. Let $E'(\text{loss})$ represent the first derivative of $E(\text{loss})$ with respect to d . The expected loss is minimized when

$$E'(\text{loss}) = c_1 P'_1(d) + c_2 P'_2(d) = 0 \quad (2)$$

The value of d (optimum dose) that satisfies this expression

$$\frac{P'_2(d)}{P'_1(d)} = -\frac{c_1}{c_2} \quad (3)$$

minimizes the total expected loss, which depends on the relative (not the absolute) losses from the initial and induced effects. It would appear that the values of relative losses may be more readily determined than absolute losses. Relative losses are quite amenable to any subsequent sensitivity analysis.

The optimum dose depends on the slopes (first derivatives) of the dose–response curves, $P_1(d)$ and

$P_2(d)$. Thus, as long as the mathematical model used for $P_1(d)$ and $P_2(d)$ approximates the true dose–response slope at low doses, the estimate of the optimum dose and relative expected loss will be fairly accurate. It is advantageous that the choices of the models are not crucial as long as the models approximate the slope of the dose–response curves in the region of the optimum dose.

Further, suppose it is of interest to find the optimum dose that minimizes the total incidence of adverse events, apart from any losses (costs) per event. Then, set $c_1 = c_2 = 1$ and the optimum dose is simply the value of d that satisfies $P'_2(d) = -P'_1(d)$.

Example for Optimum Dose of Intervention

Suppose the background probability of an illness or disease without intervention, i.e., $d = 0$, is $P_1(0) = 0.001$. Suppose a dose of one unit of the intervention product reduces the probability of the illness or disease by a factor of 2. This property is described by the negative exponential model

$$P_1(d) = 0.001 \cdot e^{-0.693d} \quad (4)$$

with a first derivative of

$$P'_1(d) = -0.000693e^{-0.693d} \quad (5)$$

Suppose the illness or disease induced by the intervention product is described by a logistic model and occurs with a background incidence of 0.0001 and one unit of the intervention product triples the background incidence

$$P_2(d) = \frac{1}{[1 + e^{(9.21-1.1d)}]} \quad (6)$$

with a first derivative of

$$P'_2(d) = \frac{1.1e^{(9.21-1.1d)}}{[1 + e^{(9.21-1.1d)}]^2} \quad (7)$$

From equation (3), the optimum dose (D) that minimizes the total expected loss is given by the solution of $P'_2(D)/P'_1(D) = -(c_1/c_2)$, giving

$$\frac{1.1e^{(9.21-1.1D)}}{[1 + e^{(9.21-1.1D)}]^2 \cdot (-0.000693e^{-0.693D})} = -c_1/c_2 \quad (8)$$

Table 1 Optimum dose (D) for various values of relative loss (c_1/c_2), estimated associated incidence of the environmentally caused disease, $P_1(D)$, the incidence of the disease induced by the intervention, $P_2(D)$, the total expected relative loss, $C(D) = [c_1 P_1(D) + c_2 P_2(D)]$, at the optimum dose, and the total expected loss for no intervention, $C(0) = [c_1 P_1(0) + c_2 P_2(0)]$, with $d = 0$

c_1/c_2	D	$P_1(D)$	$P_2(D)$	$C(D)$	$C(0)$	$C(D)/C(0)$
1/4	0.25	0.00084	0.00013	0.00136	0.00140	0.97
1/2	0.64	0.00064	0.00020	0.00104	0.00120	0.87
1/1	1.04	0.00049	0.00031	0.00080	0.00110	0.73
2/1	1.42	0.00037	0.00048	0.00122	0.00210	0.58
4/1	1.81	0.00029	0.00073	0.00189	0.00410	0.46

In this example, there is no simple analytical solution for the optimum dose (D) that minimizes the total expected loss (cost) from both illnesses or diseases. However, numerical solutions are readily attainable. Some results are illustrated in Table 1 for various values of the ratio of the relative loss (cost) of the environmentally caused illness or disease (c_1) and the relative loss (cost) induced by the intervention.

Uncertainty in the Calculation of the Optimum Dose of Intervention

In the example, if the dose–response models, $P_1(d)$ and $P_2(d)$, are correct and $c_1/c_2 = 1$, the optimum dose is 1.04 units with an expected total loss (cost) of 0.00080. However, if the ratio of the slopes of the dose responses, $P'_2(d)/P'_1(d)$, is overestimated by a factor of 4 (equivalently c_1/c_2 is underestimated by a factor of 4), a dose of 0.25 units would be selected with a total expected loss of $(0.00084 + 0.00013) = 0.00097$. This represents about a 21% increase in the total expected cost $(0.00097/0.00080)$. Similarly, if the ratios of the slopes of the dose responses is underestimated by a factor of 4 (equivalently c_1/c_2 is overestimated by a factor of 4), a dose of 1.81 units would be selected with a total expected loss of $(0.00029 + 0.00073) = 0.00102$, which is 27.5% larger than the expected total loss at the optimum dose. In this example, the total expected cost is not very sensitive to the choice of models and resulting slopes or the choice of c_1/c_2 .

Discussion

As c_1 increases relative to c_2 , the optimum dose increases, resulting in a decrease in the incidence of the initial illness or disease and accompanied by an increase in the illness or disease induced by intervention and increased reduction in the total expected loss relative to the expected total loss without intervention, $C(D)/C(0)$. If the loss (cost) of intervention is high, the optimum dose will be low and little gain over the *status quo* is accomplished. If the loss (cost) of intervention is low, then the optimum dose will be large and substantial reduction in cost relative to the *status quo* may be realized.

Additional examples with various dose–response relationships are presented by Gaylor [2].

Risk-Neutral Pricing: Importance and Relevance

In seminal papers, Black and Scholes [1] and Merton [2] (*see* **Default Correlation; Default Risk**) derived the price of an option analytically, under some regularity assumptions on the market behavior, transactions, growth etc. Although these assumptions are not often applicable in practice, however, these papers changed the way of thinking of financial markets all over the world. One of the main assumptions in their derivation, along with others, is the sublime introduction of risk-neutral measures (*see* **Equity-Linked Life Insurance**) in their calculations. They have shown that whether the market goes up or down, one can keep a portfolio risk neutral using certain strategies, such as, Δ -hedging. Finally, they calculated the price of an option, assuming growth of the portfolio at the risk-free interest rate, which gives rise to a risk-neutral measure. It became apparent that whatever is the market behavior, under risk-neutral measure, the asset price follows a discounted martingale (*see* **Insurance Pricing/Nonlife; Multistate Models for Life Insurance Mathematics**) which indicates the fair pricing. Thus, the central theme of option pricing becomes finding an equivalent risk-neutral measure under which the asset price process is a discounted martingale.

In the following, we first describe the binomial model (*see* **Volatility Smile**) due to Cox, Ross, and Rubinstein (CRR) [3] and from there analyze how it leads to the risk-neutral measure under which the asset price becomes a discounted martingale. Next, we describe the Black–Scholes [1] and Merton [2] (BSM) equations and argue that, using a suitable change of variable, the equation can be solved by using the Feynman–Kac formula relating to the heat equation in partial differential equations (PDEs). Thus, the risk-neutral measure becomes the fundamental solution of the transformed heat equation. Later, we generalize this to the multiasset scenario and models with (time varying) stochastic volatility; we then sum up with brief concluding remarks.

Binomial Model and the Risk-Neutral Measure

We first assume the following:

Assumptions

1. There are no market imperfections (no transaction costs, taxes, constraints on short sales; trading is continuous and frictionless).
2. There is unlimited borrowing and lending at rate r . Bond yield $dD = rD dt$.
3. No-arbitrage opportunity exists, i.e., no-arbitrage principle (*see* **Pricing of Life Insurance Liabilities; Premium Calculation and Insurance Pricing; Risk Measures and Economic Capital for (Re)insurers; Weather Derivatives**) is adopted.

Consider the one step binomial tree of CRR [3] with the following standard notations.

f : value of option, S : price of a stock, r : risk-free rate of interest, T : time elapsed, u : proportion of upward movement for the stock price and, d : proportion of downward movement for the same.

The activity of eliminating risk while taking a financial position is called *hedging* (*see* **Equity-Linked Life Insurance; Securitization/Life; Structured Products and Hybrid Securities; Statistical Arbitrage**). It is usually achieved by taking a simultaneous position whose risk pattern is as closely opposite to that of the original position as possible. When this is achieved perfectly, the corresponding hedge is called a *perfect hedge*, and the resultant financial portfolio is called a *riskless portfolio*. In real life, constructing such a riskless portfolio is possible only for a very short span of time.

In the context of the binomial tree, one uses portfolio weights $(-1, \Delta)$ for options and stocks. Here Δ is found, assuming that the portfolio constructed is riskless at the next unit of time, i.e., $\Delta S_u - f_u = \Delta S_d - f_d \Rightarrow \Delta = (f_u - f_d)/(S_u - S_d)$. Thus, this Δ hedging is the perfect hedge for the portfolio. Here, f_u and S_u are the options and stock prices corresponding to the up movement in one unit of time and, similarly, f_d and S_d are the corresponding prices for the down movement. To make the portfolio arbitrage-free, it should grow at the risk-free interest rate. Thus, one arrives at the next unit of time T , $e^{rT}(\Delta S_0 - f_0) = \Delta S_u - f_u$. Solving this equation

for f_0 , it is seen that

$$E(f_T) = pf_u + (1 - p)f_d = f_0 e^{rT} \quad (1)$$

and

$$E(S_T) = pS_0u + (1 - p)S_0d = S_0 e^{rT} \quad (2)$$

assuming $S_u = S_0u$ and $S_d = S_0d$, where $p = \frac{e^{rT} - d}{u - d}$. Thus, with this value of p , the expected return on the stock equals the risk-free rate.

However, this equation does not depend on the risk preference of the individuals. Thus, it appears as though we are in a world consisting of risk-neutral individuals. This is an example of a more general principle called *risk-neutral valuation* (see **Options and Guarantees in Life Insurance**) which assumes that we are operating in a “risk-neutral world”.

It is to be noted that this p is the probability of an up movement in a risk-neutral world. This may not be equal to the probability of an up movement in the real world.

Using risk-neutral valuation is convenient because we simply equate the expected return to the risk-free rate.

To generalize this model to n -steps with a finer grid of time points, say, in $\delta T = T/n$ observe, $S_{T+t} = S_t u^X d^{n-X}$, where X is the number of up moves in the market in $(t, T+t]$. Note that $ud = 1$ and $\log u = \sigma \sqrt{T/n}$ where σ is the volatility of the market. Thus $u^X d^{n-X} = e^{X\sigma \sqrt{T/n}} e^{-(n-X)\sigma \sqrt{T/n}} = e^{2X\sigma \sqrt{T/n}} e^{-\sigma \sqrt{nT}} = e^{2\sigma \sqrt{nT}(X/n - 1/2)}$. Assuming that the moves in n steps are independent and each move has two outcomes (up or down) with fixed probabilities, p for going up and $1 - p$ for going down, it follows that the distribution of X is Binomial (n, p) . Hence X follows binomial (n, p) distribution, where $p = [e^{rT/n} - e^{-\sigma \sqrt{T/n}}] / [e^{\sigma \sqrt{T/n}} - e^{-\sigma \sqrt{T/n}}] = r(T/n) + \sigma \sqrt{T/n} - (\sigma^2 T/2n) / [2\sigma \sqrt{T/n}]$ (ignoring higher powers of $(1/n)$ which is equivalent to $(1/2) + (r/2\sigma)\sqrt{T/n} - (\sigma/4)\sqrt{T/n}$. Note that, as n becomes large, X approaches the normal distribution. Thus, the mean of the normal distribution becomes

$$\begin{aligned} E \left[2\sigma \sqrt{nT} \left(\frac{X}{n} - \frac{1}{2} \right) \right] \\ = 2\sigma \sqrt{nT} \left[\left(\frac{r}{2\sigma} \right) \sqrt{\frac{T}{n}} - \left(\frac{\sigma}{4} \right) \sqrt{\frac{T}{n}} \right] \\ = \left(r - \frac{\sigma^2}{2} \right) T \end{aligned} \quad (3)$$

and the variance

$$\begin{aligned} \text{Var} \left[2\sigma \sqrt{nT} \left(\frac{X}{n} - \frac{1}{2} \right) \right] &= \frac{4\sigma^2 nT p(1-p)}{n} \\ &= 4\sigma^2 T \left(\frac{1}{4} - \left[\left(\frac{r}{2\sigma} \right) \sqrt{\frac{T}{n}} - \left(\frac{\sigma}{4} \right) \sqrt{\frac{T}{n}} \right]^2 \right) \\ &= \sigma^2 T - \left[\left(\frac{r}{2\sigma} \right) - \left(\frac{\sigma}{4} \right) \right]^2 \frac{4(\sigma T)^2}{n} \longrightarrow \sigma^2 T \end{aligned} \quad (4)$$

Therefore, as the subinterval length becomes finer and finer, i.e., as n tends to infinity, the asymptotic distribution of $2\sigma \sqrt{nT}(X/n - 1/2)$ becomes $N((r - \sigma^2/2)T, \sigma^2 T)$. Thus, the distribution of $\log(S_T) - \log(S_0)$ becomes $N((r - \sigma^2/2)T, \sigma^2 T)$. Since this argument can be carried out for any interval $(T_0, T]$, $T > T_0 \geq 0$, for $T_1 < \dots < T_k$, on the intervals $(T_i, T_{i+1}]$, it follows that that distribution of $\log(S_{T_{i+1}}) - \log(S_{T_i})$ is $N((r - \sigma^2/2)(T_{i+1} - T_i), \sigma^2(T_{i+1} - T_i))$ and for disjoint intervals they are independent. Now taking a linear transformation of these variables as $Y = AZ$, where components of Z are differences of log prices, and hence are independent and, for $i \geq 1$, Z_{i+1} has mean $(r - \sigma^2/2)(T_{i+1} - T_i)$ and variance $\sigma^2(T_{i+1} - T_i)$ with Z_1 having mean $(r - \sigma^2/2)T_1$ and variance $\sigma^2 T_1$, where

$$A = \begin{bmatrix} 1 & 0 & 0 & 0 & \dots & 0 \\ 1 & 1 & 0 & 0 & \dots & 0 \\ 1 & 1 & 1 & 0 & \dots & 0 \\ \vdots & \vdots & \vdots & \vdots & \dots & \vdots \\ 1 & 1 & 1 & 1 & \dots & 1 \end{bmatrix} \quad (5)$$

the joint distribution of $\{\log(S_{T_i}) : i = 1, \dots, k\}$ becomes k -variate normal with mean $(r - \sigma^2/2)T_i$ and variance $\sigma^2 T_i$, for $i = 1, \dots, k$ and the (i, j) th element of the correlation matrix $\sqrt{T_i/T_j}$ for $i \leq j$, as $\log(S_{T_j}) = \log(S_{T_i}) + [\log(S_{T_j}) - \log(S_{T_i})]$, and the first term is independent of the second term. Since the finite-dimensional distribution of $\log(S_T/S_0)$ agrees with that of Brownian motion, with means and variances as mentioned above, and both are continuous processes, one can now perceive S_T as distributionally equivalent to $S_0 \exp \{(r - \sigma^2/2)T + \sigma W_T\}$, which is the risk-neutral model, where W_T is the standard Brownian motion. Thus the price of an European option (see

Insurance Pricing/Nonlife), under the above assumption, can be found by finding the expectation of the payoff with respect to the risk-neutral measure of the S_T process, i.e., with respect to the measure of $S_0 \exp \{(r - \sigma^2/2)T + \sigma W_T\}$ process. (For an introductory exposition to binomial trees and option pricing, see Ross [4].)

Notice that the above argument and the use of Itô's lemma assert that, under risk-neutral measure, $\{S_t\}$ satisfies the following stochastic differential equation (SDE).

$$dS_t = rS_t dt + \sigma S_t dW_t \quad (6)$$

Had we started with the market growth (probability) model, i.e., $p_\mu = \frac{e^{\mu T} - d}{u - d}$, our argument would have led to an SDE,

$$dS_t = \mu S_t dt + \sigma S_t dW_t \quad (7)$$

which is assumed to be the market model of stock price in Black–Scholes.

Now, similar to the discrete time model, if the portfolio weights for options and stocks are $(-1, \Delta)$, then the value of the portfolio is $V = -f + \Delta S$. To keep the portfolio riskless at any time t , one should observe that $\partial V / \partial S = 0$. Thus, solving Δ , one gets $\Delta = \partial f / \partial S$, which is the continuous version of the discrete analog $\frac{f_u - f_d}{S_u - S_d}$. Then, at a time t , growth of the value should be at the rate of risk-free interest, $V_t = e^{rt} V_0$, i.e., $dV_t = rV_t dt$, to avoid arbitrage opportunity. Now, from the market model, $dV = -df + \frac{\partial f}{\partial S} dS$, using Itô's lemma on f , one finds $df = \frac{\partial f}{\partial t} dt + \frac{\partial f}{\partial S} dS + \frac{1}{2} \frac{\partial^2 f}{\partial S^2} (dS)^2$. Thus, $-df + \frac{\partial f}{\partial S} dS = -\frac{\partial f}{\partial t} dt - \frac{1}{2} \frac{\partial^2 f}{\partial S^2} \sigma^2 S^2 dt$. Therefore, using the risk-free model of V , i.e., $dV_t = rV_t dt = r(-f + \frac{\partial f}{\partial S} S) dt$, one arrives at the Black–Scholes [1]–Merton [2] (BSM) differential equation

$$\frac{\partial f}{\partial t} + rS \frac{\partial f}{\partial S} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 f}{\partial S^2} = rf \quad (8)$$

Note that this equation does not involve any information on the risk attitude of the investors. The Black–Scholes–Merton (BSM) differential equation would depend on risk preference if it involved μ (expected rate of return on the stock). Thus, in this context, for all practical purposes we can assume that all investors are risk neutral. Thus the expected rate of return will simply be the rate r . Making a change of

variable in this equation as

$$\tau = T - t, z = a \log S + b\tau, \text{ and } f = e^{c\tau} g(z, \tau) \quad (9)$$

for a, b and c to be determined later, we get

$$\begin{aligned} \frac{\partial f}{\partial t} &= \frac{\partial e^{c\tau}}{\partial t} g + e^{c\tau} \frac{\partial g}{\partial \tau} \frac{\partial \tau}{\partial t} + e^{c\tau} \frac{\partial g}{\partial z} \frac{\partial z}{\partial t} \\ &= -ce^{c\tau} g - e^{c\tau} \frac{\partial g}{\partial \tau} - be^{c\tau} \frac{\partial g}{\partial z} \end{aligned} \quad (10)$$

$$\frac{\partial f}{\partial S} = e^{c\tau} \frac{\partial g}{\partial z} \frac{\partial z}{\partial S} = \frac{ae^{c\tau}}{S} \frac{\partial g}{\partial z} \quad (11)$$

$$\begin{aligned} \frac{\partial^2 f}{\partial S^2} &= \frac{\partial}{\partial S} \left(\frac{ae^{c\tau}}{S} \right) \frac{\partial g}{\partial z} + \frac{ae^{c\tau}}{S} \frac{\partial}{\partial S} \left(\frac{\partial g}{\partial z} \right) \\ &= -\frac{ae^{c\tau}}{S^2} \frac{\partial g}{\partial z} + \frac{a^2 e^{c\tau}}{S^2} \frac{\partial^2 g}{\partial z^2} \end{aligned} \quad (12)$$

Thus, the BSM equation becomes

$$\begin{aligned} 0 &= \frac{\partial f}{\partial t} + rS \frac{\partial f}{\partial S} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 f}{\partial S^2} - rf \\ &= -(r + c)e^{c\tau} g - e^{c\tau} \frac{\partial g}{\partial \tau} + \left(ar - b - \frac{1}{2} a \sigma^2 \right) \\ &\quad \times e^{c\tau} \frac{\partial g}{\partial z} + \frac{1}{2} \sigma^2 a^2 e^{c\tau} \frac{\partial^2 g}{\partial z^2} \end{aligned} \quad (13)$$

Now taking $c = -r, b = a(r - \frac{1}{2}\sigma^2)$ and $a = 1$ and dividing both side by, $e^{c\tau}$ we obtain

$$\frac{\partial g}{\partial \tau} = \frac{1}{2} \sigma^2 \frac{\partial^2 g}{\partial z^2} \quad (14)$$

Thus, having an initial data, $g(z, 0) = f(S, T) =$ payoff, say, one can solve the initial value problem of the heat equation, using the Feynman–Kac formula as

$$\begin{aligned} g(z, \tau) &= E(g(Z_\tau, \tau) | Z_0 = z) = E(\text{payoff}) \\ &= \int_{-\infty}^{\infty} \text{payoff}(y) p(z, \tau, y) dy \end{aligned} \quad (15)$$

where $p(z, \tau, y)$ is the fundamental solution of the equation and is given by $p(z, \tau, y) = \frac{1}{\sigma \sqrt{2\pi\tau}} \exp\{-(y - z)^2 / 2\sigma^2 \tau\}$ which is the density of the Brownian motion, starting at z with drift zero and diffusion coefficient σ^2 . Now, getting back to the original variable, one arrives at the solution that is described above with respect to the risk-neutral measure (for details, see Kallianpur and Karandikar [5]).

Though risk-neutral valuation is an artificial device for obtaining solutions to the BSM differential equation, the solutions are valid in all worlds. When we move to the real world, both the growth rate of a stock and the discount rate changes but fortunately, they do so in opposite directions and at exactly equal magnitudes to offset each other.

This principle can then be applied to pricing forward contracts or options with known dividend yields also.

Equivalent Martingale Measure (EMM)

In the last section, we discussed the asset pricing theories implicitly, by using equivalence of no-arbitrage principle and the existence of a measure under which the price process is a discounted martingale. Naturally, this leads us to the discussion of existence of an equivalent martingale measure (EMM) (*see Insurance Pricing/Nonlife; Mathematical Models of Credit Risk*) in a broader perspective. EMM is a probability distribution under which the price processes is adjusted to be consistent with no-arbitrage principle and attain risk neutrality. Harrison and Kreps [6] show that under the EMM, the stock price process is a martingale. Accordingly, the risk-neutral pricing method is also called the *martingale pricing technique*.

Consider derivatives dependent only on one variable θ : $\frac{d\theta}{\theta} = m dt + s dW$. Suppose, for simplicity, f_1 and f_2 are two derivatives $f_j = f_j(\theta, t)$, $j = 1, 2$.

$$\frac{df_j}{f_j} = \mu_j dt + \sigma_j dW, \quad \mu_j = \mu_j(\theta, t),$$

$$\sigma_j = \sigma_j(\theta, t), \quad j = 1, 2 \quad (16)$$

No-arbitrage principle and usual riskless portfolio construction implies

$$\frac{\mu_1 - r}{\sigma_1} = \frac{\mu_2 - r}{\sigma_2} = \lambda \quad (17)$$

where λ is called the *market price of risk*. Then the model becomes

$$\frac{df_j}{f_j} = (r + \lambda \sigma_j) dt + \sigma_j dW \quad (18)$$

This can be extended to several state variables $\theta_1, \theta_2, \dots, \theta_n$ as follows: $\frac{d\theta_i}{\theta_i} = m_i dt + s_i dW_i$, $i = 1, \dots, n$, and $f_j = f_j(\theta_1, \theta_2, \dots, \theta_n)$: $\frac{df_j}{f_j} = \mu_j dt + \sum_{i=1}^n \sigma_{ij} dW_i$. We similarly have $\mu_j - r = \sum_{i=1}^n \lambda_i \sigma_{ij}$: extent of excess return required (see Hull [7]).

The following example illustrates the EMM result:

Consider two traded securities f and g and a derivative $\phi = \frac{f}{g}$. Suppose the market price of risk is $\lambda = \sigma_g$, volatility of g . Then

$$\frac{df}{f} = (r + \sigma_g \sigma_f) dt + \sigma_f dW \quad (19)$$

$$\frac{dg}{g} = (r + \sigma_g^2) dt + \sigma_g dW \quad (20)$$

Now, it can be shown that

$$d\phi = d\left(\frac{f}{g}\right) = (\sigma_f - \sigma_g) \frac{f}{g} dW \quad (21)$$

$$\text{or} \quad \frac{d\phi}{\phi} = (\sigma_f - \sigma_g) dW \quad (22)$$

which is a martingale (this can be posed as an application of Girsanov's theorem).

When there are no-arbitrage opportunities, $\phi = \frac{f}{g}$ is a martingale for any security f , for some choice of market price of risk that is given by the volatility of the numeraire security g . This world is referred to as forward risk neutral with respect to g .

Models of Changing Volatility

Empirical studies show that GBM is not an appropriate model for some financial instruments: skewness, excess kurtosis, serial correlation, and time-varying volatilities are some of the observed features of data that do not conform with the properties of GBM.

Among the solutions proposed, time-varying volatility models have received the most attention as σ plays such a crucial role in the BSM formulation.

If $\sigma = \sigma(t)$, a known function of time, then in the BSM formula, we can replace σ by $\int_t^T \sigma_s ds$. But if σ is stochastic, e.g., given by the model

$$\frac{d\sigma}{\sigma} = \mu dt + \sigma dW_p \quad (23)$$

and

$$d\sigma = \alpha(\sigma) dt + \beta(\sigma) dW_\sigma \quad (24)$$

with $dW_p dW_\sigma = \rho dt$ (instantaneous correlation) and α and β are specified functions, then such models are called *stochastic volatility models*. These models represent an incomplete market, where pricing depends on risk premium of the volatility. Even so, for some

models, a pricing formula may be derived (see, for instance, Heston [8]). Derivation of the pricing rule is not always feasible, as formation of a replicating portfolio (see **Solvency**) is not, in general, possible. If $\rho = 0$ then, this can be done as in the following model due to Hull and White [9]:

$$\frac{dp}{p} = \mu dt + \sigma dW_p \quad (25)$$

and

$$\frac{d\sigma^2}{\sigma^2} = \alpha dt + \xi dW_\sigma \quad (26)$$

With these models, one can price the derivative using the EMM technique, with volatility as a non-traded security.

Direct estimation in continuous time is very difficult but a discrete approximation by Nelson [10, 11], which is inspired by pioneering works in the literature on ARCH (see **Extreme Value Theory in Finance**), GARCH, and EGARCH formulation by Engle [12] and later by Bollerslev [13], Bollerslev *et al.* [14], and others, works well in practice. Therefore, the other possibility is to start with a discrete-time model for the dynamics of the asset price, governed by an ARCH model, and then, to derive the corresponding formulae. This is, naturally, easier to implement. However, some issues like nonlinearity and state dependence are very hard to handle theoretically in the discrete setting, although they are easier in the continuous-time framework. With the advent of powerful personal computers, numerical methods with various sophisticated discretization techniques using binomial/trinomial trees, ARCH/GARCH models are not beyond the realm of achievement any more [15].

Conclusion

The concept of the risk-neutral measure is a very powerful and important tool in financial modeling. The basis of the approach lies in the *Feynman–Kac heat PDE*, and it has now become a commonly used term in financial markets thanks to the seminal work of Black and Scholes [1, 2]. With the advent of powerful computers, this has become an even more important

tool, nowadays. We have given a brief description of the model, its variants, and applications. A detailed study would be voluminous, and the interested reader is referred to the literature cited above.

GOPAL K. BASAK AND DIGANTA MUKHERJEE

Role of Alternative Assets in Portfolio Construction

Motivation

In this paper, we discuss the role of alternative investments within the context of asset allocation for long-term investors. We define alternative assets as the most popular private securities/contracts – hedge funds (*see* **Asset–Liability Management for Life Insurers; Alternative Risk Transfer**); managed futures (commodities, currency, and fixed income); and private equity (venture capital and leveraged buy-outs). These asset categories cover a wide assortment of investment strategies [1–4]. For example, there are over a dozen subcategories of hedge funds. Unfortunately, it has been difficult to measure the annual temporal performance of private equity for portfolio models; we do not focus on these securities. The recommendations apply to fully integrated risk-management systems (i.e., asset and liability management) with suitable extensions [5].

Alternative asset categories have become increasingly popular with institutional and wealthy individual investors since the recession in 2000–2001. The trend has been caused by several interrelated factors, including the superior performance achieved by leading university endowments over the past decade, and the need to recover lost surpluses by pension trusts (among others). Top university endowments in the United States (e.g., Yale, Harvard, Princeton, and Stanford Universities) and other leading institutional investors have achieved 15 to over 20% annual returns over the past decade by shifting a large proportion of their capital to private investments. In contrast, especially since 2000, numerous pension trusts have fallen behind, with many funding ratios dropping to the 75–80% range [6].

A major benefit of the alternative investments involves the generation of return patterns that differ from factors that affect equity and bond markets. In particular, stocks and bonds are largely driven by three generic factors: (a) government (default free) interest rates, (b) corporate earnings as a proxy for the level of economic activities, and (c) a risk premium [7, 8]. Thus, an investor's diversification is limited because of the dependence on a relatively

small number of underlying driving factors. Diversification becomes much less during periods of economic instability and contagion owing to an increase in risk premium.

A second potential benefit of alternative assets, especially for private markets such as venture capital, is the ability to increase leverage while smoothing price variations over several years. By their structure, some private market securities, e.g. early stage ventures, are not subject to the fluctuations of liquid market-based instruments. Owing to lack of reporting on reliable returns on a regular basis, there is difficulty in analyzing these asset categories within an optimal portfolio model. Future research should be aimed at this domain (see section titled “Summary and Future Directions”). Accordingly, we focus on nontraditional assets possessing marketable securities in this paper.

For simplicity, we discuss the role of alternative investments for asset-only allocation models. To properly address an investor's circumstance, we advocate a comprehensive asset and liability model (ALM) (*see* **Actuary; Risk Measures and Economic Capital for (Re)insurers**) such as, among others, described in Consigli and Dempster [9, 10], Mulvey *et al.* [11], and Ziemba and Mulvey [5].

Multiperiod Portfolio Models

This section provides a brief explanation on benefits of adopting multiperiod models, especially fixed-mix policy rules, for portfolio construction. There are distinct advantages (*see* **Credit Migration Matrices; Asset–Liability Management for Nonlife Insurers**) of a multiperiod horizon as compared with a static buy-and-hold framework [12, 13]. First, the multiperiod model can address a number of significant real-world issues, such as transaction costs (e.g. taxes) and changing economic environments (growth *versus* recession) with nonconstant correlation and covariance matrices. For instance, stock and bond returns are generally positively related under normal economic conditions, whereas these returns can become negatively related during and after a recession. A multiperiod portfolio model can show the impact of these changing conditions on the investor's future wealth in an integrated risk fashion. Also, the performance of a multiperiod model can be greater than the performance of a buy-and-hold model for

comparable planning horizons because of the gains attained by rebalancing the portfolio (*see Equity-Linked Life Insurance; Informational Value of Corporate Issuer Credit Ratings*) at selected time junctures. References [13–16] discuss the nature of the rebalancing gains.

There is a major drawback, however, to implement a multiperiod model: the model can be non-convex, which makes it difficult to attain the optimal strategy. Instead of complicated optimization techniques, we provide a simple, yet efficient, approach – fixed-mix policy rule – to illustrate the benefits of multiperiod horizon. The fixed-mix strategy always applies the same weights at the beginning of the time period to constituents, in contrast to the buy-and-hold approach, where the weights vary as the prices of constituents change over time. Also, the fixed-mix strategy can serve as a benchmark for other dynamic strategies.

Early on, Samuelson [17] and Merton [18] showed that the fixed-mix investment rule is optimal under certain restrictive assumptions. Mulvey *et al.* [19], among others, presents a clear illustration for the connection between the fixed-mix rule and rebalancing gain. For simplicity, let us assume that there is one stock and one risk-free asset. Suppose the stock price process P_t follows a geometric Brownian motion that can be represented by the equation

$$dP_t = \alpha P_t dt + \sigma P_t dz_t \quad (1)$$

where α is drift, σ is volatility, and z_t is a Brownian motion with mean zero and variance t . Similarly, risk-free asset B_t follows the same process with drift equal to zero and volatility equal to zero. Then the stochastic differential equation (*see Numerical Schemes for Stochastic Differential Equation Models*) for B_t can be written as

$$dB_t = rB_t dt \quad (2)$$

Now, assume that we invest η in the stock and $(1 - \eta)$ in the risk-free asset with the fixed-mix policy rule. Then the wealth process of the portfolio W_t can be expressed as

$$\frac{dW_t}{W_t} = \frac{\eta dP_t}{P_t} + \frac{(1 - \eta) dB_t}{B_t} \quad (3)$$

After substituting for P_t and B_t in the equation, one can show that the growth rate of the portfolio is

$$\gamma_w = \eta\alpha + (1 - \eta)r - \frac{\eta^2\sigma^2}{2} \quad (4)$$

For simplicity, we assume that the growth rate of the stock and the risk-free asset are equal.^a Then the growth rate of the portfolio can be rewritten as

$$\gamma_w = r + \frac{(\eta - \eta^2)\sigma^2}{2} \quad (5)$$

If $0 < \eta < 1$, this quantity is greater than the growth rate of the buy-and-hold approach by $(\eta - \eta^2)\sigma^2/2$. The quantity corresponds to the rebalancing gain due to the application of the fixed-mix policy rule as compared with buy-and-hold.

Many investors have applied versions of the fixed-mix rules with practical successes [5, 11, 16, 20–22]. For example, the famous 60/40 norm (60% equity and 40% bonds) falls under this policy. Here, at each period, we rebalance the portfolio to 60% equity and 40% bond. Another good example is Standard & Profit 500 equal-weighted index (S&P EWI) by Rydex Investments. As opposed to traditional cap-weighted S&P index, stocks have the same weight (1/500) and the index is rebalanced semiannually to maintain the weights over time. To illustrate the benefits of applying the fixed-mix policy rule, during 1994–2005, S&P EWI achieved 2% excess return with only 0.6% extra volatility compared to S&P 500 index. Figure 1 illustrates log prices of S&P 500 and S&P EWI for last 4 years.

We close this section by discussing desirable properties of assets in order to achieve rebalancing gain. First, suppose two assets in the derivation above are perfectly correlated. Then, it can be easily shown that the rebalancing gain is zero. From this, it is evident that diversification among assets plays a major role to achieve an excess growth rate. This observation suggests that dynamic diversification is essential in order to produce extra gains *via* multiperiod approaches. Also, as always, diversification provides a source of reducing portfolio risk. Second, given a set of independent assets, the rebalancing gain $((\eta - \eta^2)\sigma^2/2)$ increases as the volatilities of assets increase. To benefit from rebalancing gain, the volatility of each asset should be reasonably high. In this context, the traditional Sharpe ratio (*see Axiomatic Models of Perceived Risk; Longevity Risk and Life Annuities*) might not be a good measure for individual asset in terms of multiperiod portfolio management, even though it remains valid at the portfolio level. Additionally, low transaction costs (fees, taxes, etc.) are desirable because applying the fixed-mix policy rule requires portfolio rebalancing.

Figure 1 Log prices of S&P 500 index and S&P EWI during July 2003 to December 2006. This figure illustrates the log-price processes for S&P EWI and S&P 500 from July 2003 to December 2006. Each index is scaled to have a log price of zero at the beginning of the sample period. In term of the total return, S&P EWI outperformed S&P 500 index for last 4 years and this performance difference between the two assets can be interpreted as a rebalancing gain due to the fixed-mix policy rule

In summary, the properties of the best ingredients for the fixed-mix rule are (a) relatively good performance (positive expected return), (b) relatively low correlations among assets, (c) reasonably high volatility, and (d) low transaction costs. For more detailed discussion, see Fernholz [14] and Mulvey *et al.* [19].

Historical Perspective

In this section, we describe the performance of several major categories of alternative investments along with traditional assets over a recent 12-year historical period. While there are obvious limitations of evaluating historical performance, there is benefit for observing the past patterns. Figure 2 and Table 1 depict historical performance of some of the major traditional asset categories and alternative assets including an aggregate hedge-fund index, managed futures index, a long/short equity fund index, and a currency-based index.

There are several general observations. First, the historical record is limited for most alternative assets. For instance, before 1994, the hedge-fund industry was quite small and the indices did not adjust for

survivor bias. In the future, because of the explosive growth in hedge funds, returns may decrease by reducing the attainable edge for certain strategies, such as statistical arbitrage (*see Statistical Arbitrage; Ethical Issues in Using Statistics, Statistical Methods, and Statistical Sources in Work Related to Homeland Security*). Given these limitations, the overall performance of the alternative assets was generally contained within the coverage of traditional equities, bonds, and real-estate investment trusts (REITs). The returns and risks are roughly compatible between traditional and alternative indices.

Several studies have conducted performance attribution of the return patterns of selected alternative assets, mostly hedge funds [2, 23, 24]. This research helps investors understand the process undertaken by their portfolio managers (at least at a high level). If an investor can find a pattern that is a reasonably consistent match, the portfolio manager could be compensated by comparison to this benchmark, perhaps, in addition to the usual absolute return benchmarks. Also, the development of economic scenario generating systems requires a linkage of economic factors to the returns of the asset categories (both traditional and alternative) [10].

Traditional asset classes		
Type	Name	Description
Equity	S&P 500	Standard and Poor 500 index: An unmanaged cap-weighted index of 500 domestic stocks.
	S&P EWI	Rydex S&P 500 equal weighted index: The fixed-mix version (equal weight) of S&P 500 index.
	EAFE	Morgan Stanley equity index for Europe, Australia, and the Far East: An unmanaged cap-weighted index of overseas stocks.
Bond	LB Agg.	Lehman long aggregate bond index: an unmanaged index of government & corporate bonds, mortgage-backed securities and asset-backed securities.
	Strips	20-year U.S. government zero-coupon bonds.
	T-bill	U.S. government 30-day Treasury bill
Real Estate	NAREIT	National association of real-estate investment trusts: an unmanaged index of U.S. real estates.
Commodity	GSCI	Goldman Sachs commodity index: a composite index of long-only commodity futures
Alternative asset classes		
Type	Name	Description
Hedge Fund	Hedge. Fund Ind.	Tremont hedge-fund aggregate index: an asset-weighted hedge-fund index which is net of fees and expenses.
	Man. Fut. Index	Tremont managed futures index: an asset-weighted hedge-fund index of investments in listed bond, currency, equity and commodity futures markets.
	Tremont L/S	Tremont long/short equity index: an asset-weight hedge-fund index of investments on both the long and short sides of equity markets.
Currency	Currency Index	Reuters-CRB Currencies Index: an index of five currency futures (BP, EC, CD, SF and JY).

Figure 2 Performance of alternative and nonalternative asset categories (1994–2005). Among 12 categories, four assets – Tremont hedge-fund aggregate index (Hedge-Fund Ind.), Tremont long/short equity index (Tremont L/S), currency index, and Tremont managed futures index (Man. Fut. Index) – are classified as alternative asset classes. Unlike traditional assets, each fund in these categories has a specific benchmark. That is, the money manager of a specific fund is asked to outperform the corresponding benchmark such as S&P 500 or Russell 1000, while constructing her portfolio similar to the benchmark. Thus, performance of such alternative assets is highly dependent on their underlying benchmark. Therefore, a direct comparison between traditional and alternative assets is not straightforward. However, since we focus on the alternative assets as a genuine source of diversification rather than superior performance, we illustrate the historical performance of such assets along with traditional ones to give a general idea to the readers. See end note (a) for the detailed explanation of each asset

Table 1 Summary statistics for historical performance of popular asset categories. In this table, investment performance of each asset category for whole sample period (top), the first 6-year (middle), and the second 6-year (bottom) is shown. Assets with relatively high maximum drawdown are highlighted. For detailed description of each asset, see the legend in Figure 1

	Annualized return (%)	Standard deviation (%)	Sharpe ratio	Maximum drawdown (%)	Return/ Drawdown
<i>Whole sample period (1994–2005)</i>					
S&P 500	10.5	14.8	0.45	44.7	0.24
LB agg.	6.8	4.5	0.66	5.3	1.29
EAFE	6.8	14.5	0.20	47.5	0.14
T-bills	3.8	0.5	0.00	0.0	N/A
NAREIT	13.1	13.1	0.71	26.3	0.50
GSCI	10.1	20.1	0.31	48.3	0.21
Hedge-Fund Ind.	10.7	7.9	0.87	13.8	0.77
Man. Fut. Index	6.4	12.1	0.21	17.7	0.36

Next, we briefly review the historical performance of the asset categories over two distinct subperiods. We designate the first period January 1, 1994 to December 31, 1999 as “high equity”, whereas the second period January 1, 2000 to December

31, 2005 indicates “low equity”. Over the entire 12-year period, the annual returns for the asset categories range from low = 2.6% (for currencies) to high = 13.1% (for REITs). Many assets display disparate behavior over the two 6-year subperiods:

the Goldman Sachs commodity index (GSCI) and REITs had their worst showing during the first subperiod – the lowest returns and highest drawdown values, whereas EAFE and S&P 500 display the opposite results – high returns in the first subperiod. As a general observation, investors should be ready to encounter sharp drops in individual asset categories. Drawdown for half of the categories lies in the range 26–48% (Table 1).

Two of the highest historical return-to-risk ratios occurred in the hedge-fund categories: (a) the Tremont aggregate hedge-fund index (0.87) and (b) the Tremont long/short index (0.78). In both cases, returns are greater than the S&P 500 index with much lower volatility. As mentioned, this performance has led to increasing interest in hedge funds. Many experts believe that the median future returns for hedge funds are likely to be lower than historical values – due in part to the large number of managers entering the domain. In fact, low volatility may be a detriment for increasing overall portfolio performance since it limits the rebalancing gains. There are advantages in combining assets with modest return-to-risk ratios and reasonable returns in a rebalanced portfolio, when the lower ratio is caused by higher volatility.

In summary, alternative assets have displayed solid performance over the 12-year period, 1994–2005, especially the Tremont aggregate hedge-fund and long/short indices. In both cases, however, the returns in the second period, while remaining positive, fell substantially, partially because of the lower returns of equities. In contrast, the currency index and managed futures showed the opposite relationship – higher returns in the second period. The latter assets showed countercyclical behavior as compared with equities. As mentioned, there is some concern that returns will drop further with the recent expansion of the alternative investment universe. Even in this environment, alternative investments can provide benefits to the investor as a novel source of diversification, as we will see in the next section.

The Role of Alternative Assets in the Portfolio Management

As mentioned, there is evidence that private markets can generate superior returns as compared

with many public markets [25]. Unfortunately, for most investors, top opportunities are rarely available without special access privileges. These accessibility issues are slowly receding with the recent introduction of tradable hedge funds and related instruments (such as active exchange traded funds), which allow individual investors to gain a portion of the median hedge-fund returns.

Importantly, alternative investments can provide the benefits of wide diversification and leverage to achieve superior performance. In this section, we are less concerned with superior performance; we use the alternative assets to provide additional sources of diversification – above and beyond that dictated by equities and bonds.

The most comprehensive approach for evaluation of alternative assets in a portfolio is to apply an integrated risk-management system on a set of investment vehicles, which includes alternative asset classes. However, such an approach is beyond the scope of this article. Thus, rather than conducting an ALM optimization, we apply the fixed-mix rule to the assets mentioned in the previous section. More specifically, the analysis will construct three portfolios: (P1) a buy-and-hold portfolio of only traditional assets, (P2) a buy-and-hold portfolio of traditional and alternative assets, and (P3) a fixed-mix portfolio of both traditional and alternative assets. In this regard, we use the fixed-mix rule at two levels. First at the stock selection level, we substitute an equal-weighted S&P 500 index for the capital-weighted S&P 500 fund. The equal-weighted index has generated better performance over the standard S&P 500 index [21], as would be expected owing to the additional returns gotten from rebalancing the mix. Then, the portfolio is rebalanced monthly to fulfill the fixed-mix policy rule at the asset selection level. For simplicity, assets are weighted equally for all three portfolios. Table 2 summarizes these strategies.

We first compare P1 and P2 to illustrate the diversification benefits from the alternative asset categories. The two leftmost columns of Table 3 show the resulting performance. Here, the historical performance of P1 and P2 is 9.9 and 9.4% per year, with annualized volatility equal to 7.9 and 6.6%, respectively. As expected, alternative assets serve as a novel source of diversification, resulting higher risk-reward ratios for P2. The benefit of including alternative assets becomes even greater when the fixed-mix rule is used. Among three portfolios,

Table 2 Portfolio description

Portfolio	Description	Constituents
P1	Traditional assets only (buy-and-hold)	Traditional assets: S&P 500, LB bond, EAFE, NAREIT, GSCI, STRIPS
P2	With alternative assets (buy-and-hold)	Traditional assets: S&P 500, LB bond, EAFE, NAREIT, GSCI, STRIPS Alternative assets: man futures, hedge-fund index, L/S index, currency
P3	With alternative assets (fixed mix)	Traditional assets: S&P EWI, LB bond, EAFE, NAREIT, GSCI, STRIPS Alternative assets: man futures, hedge-fund index, L/S index, currency

P3 shows the best performance in most of performance measures. Clearly, wide diversification pays off in terms of reducing the portfolio's overall risk – volatility and maximal drawdown. The maximum drawdown for P3 is mere 6.4%, which is almost half of that for P1. Also, improvements in return–risk ratios are significant, especially the return–drawdown ratio (from 0.89 to 1.54). It is also worth noting that the performances of P3 in each of the two sub-periods (1994–1999 and 2000–2005) are relatively similar, which implies that it provides more reliable outcomes.

Next, we take three portfolios and apply selected degrees of leverage at several values: 20, 50, and 100%. Leverage is achieved in the conventional way by borrowing money at the T-bill rate and putting it accordingly on the constituents. Because three portfolios in consideration do not include T-bill, the relative weights do not change as the portfolio is levered. The returns increase for each juncture with increasing risks (as measured by volatility and drawdown). However, for the fixed-mix portfolio with alternative assets (P3), the overall risks are quite reasonable even at the 100% leverage – 12.4% annualized volatility and 14.4% drawdown – resulting in better risk–reward ratio than the other portfolios. Interestingly, P3 outperforms P1 with no leverage in terms of return–risk ratios, even at 100% leverage. Efficient frontiers in Figure 3 clearly illustrate this point. See Mulvey *et al.* [19] for further improvements via overlay strategies.

The historical results suggest that investors can benefit by including alternative assets in their portfolio. First, an investor with access to the top deals can achieve truly superior performance – for example,

Renaissance Technologies' annual return of over 35% after fees since 1989. Similarly, the leading U.S. university endowments have shown that private investments can be highly profitable. But also significantly, alternative assets offer the benefits of combining wide diversification and targeted leverage. These advantages are more readily available for most investors than gaining access to the top private investments.

There are two qualifiers for this empirical study: (a) the historical performance of alternative investments may not correspond to future performance owing to, among others, the increase in the number of hedge funds existing today, and (b) it can be difficult to rebalance a portfolio because of restriction on the entry and exit of capital within many of the private markets. Accordingly, the empirical results should be treated as an illustration of possible benefits. This issue is expected to be partially resolved in near future owing to emergence of new financial instruments such as active exchange traded funds. The main message remains – alternative investments can provide increasing diversification benefits because of the uniqueness of the return patterns.

Summary and Future Directions

The top alternative investments have delivered superior performance over the past 10–15 years, as shown by the returns of leading university endowments and the consistently high returns of selected hedge funds. Unfortunately, most investors are unable to gain access to these opportunities at this time.

The report suggests that, with careful risk management, investor performance can be improved by adding alternative assets to a portfolio of traditional

Table 3 Historical results with different leverage values applied to portfolios. In this table, historical investment performance of three portfolios is illustrated for the whole sample period (1994–2005, top row), the first 6-year subperiod (1994–1999, middle row), and the second subperiod (2000–2005, bottom row). Performance of P1, P2, and P3 are shown in the left, middle, and right column, respectively. As anticipated, P3 outperforms both P1 and P2, which depicts the benefits of including alternative assets as well as adopting multi-period models. Performance improvements are most significant in the return–drawdown ratio. Also, the fixed-mix portfolio with alternative assets (P3) shows the best return–risk ratios as it gets levered up

Figure 3 Efficient frontiers (see *Asset–Liability Management for Nonlife Insurers*) of the portfolios with/without alternative assets. Figure (a) illustrates efficient frontiers in volatility–return plane, while (b) is drawn in maximum drawdown–return plane. The efficient frontier of P3 contains those of P1 and P2 in both cases, which clearly exhibit the role of alternative assets in portfolio construction

asset categories. Alternative assets can provide reasonable performance with less dependency on the usual economic factors such as corporate earnings, interest rates, and risk premium. The novel return patterns provide a substantial benefit for increasing diversification. For long-term investors, wide diversification can be coupled with target leverage to increase portfolio performance. Rebalancing gains are also available for selected investors. As always, investors should carefully analyze their potential risks and rewards in an integrated, anticipatory fashion.

What are directions for future research? First, we can continue to search for assets with novel sources of returns (as compared with stocks, bonds, and money market securities). A prime example involves weather-related products. Ideally, the emerging securities would develop in liquid markets so that investor has valid market prices and can achieve rebalancing gains.

In addition, research can be aimed at improving the modeling/pricing of private securities. Current approaches, such as the internal rate of returns for seasoned (vintage year) ventures, are not so helpful for the problem of seeking an optimal asset allocation. Approaches developed for asset allocation (and integrated risk management) under traditional categories will need to be extended for the inclusion of their privately held investments/securities.

Undoubtedly, long-term, multiperiod financial planning models for individual investors will continue to grow in popularity. The aging population of wealthy individuals will require assistance as they approach retirement and also for estate planning purposes. The U.S. government has recently passed legislation that makes it easier for financial organizations to provide probabilistic investment advice. This change in regulation has already led to implementation of a number of stochastic planning systems (similar to the ones discussed in this paper). Individual and institutional investors alike can benefit by applying integrated risk-management systems in conjunction with a full set of traditional and alternative asset categories.

End Notes

- ^a. This assumption is *not* required to illustrate the rebalancing gain, but it makes the illustration simpler and easier to understand.

JOHN M. MULVEY AND WOO CHANG KIM

Role of Risk Communication in a Comprehensive Risk Management Approach

The ability of humankind to intuitively assess and manage risks has been fundamental for human survival and evolution. Those who were adept at recognizing risk and learning from danger survived to reproduce, whereas those who could not inevitably perished from avoidable environmental hazards [1]. However, the risks of concern to people have changed dramatically in the last 30–40 years. While people were previously concerned about major risks with visible and often drastic consequences (such as polio and physical hazards associated with various types of employment like mining), resolution of these high magnitude hazards resulted in a shift of concern to risks that were less visible, more poorly understood, and inherently more frightening because of their unknown nature (such as pesticides). This gave rise to a more “formal” practice of quantitative risk assessment in the early 1980s [2] (*see Environmental Health Risk Assessment; Environmental Hazard; Risk and the Media*).

The assessment and subsequent management of these risks has burgeoned into a distinct field of scientific study and public policy. In recent years, the effective management of risks to human health posed by potentially hazardous environmental contaminants or situations has commanded more public attention and reaction as risk issues and the related scientific information have become more complex and multifaceted (*see Environmental Hazard*). As various agencies and organizations struggled to deal with a public that was increasingly apprehensive and distrustful about these risks, the critical role of effective communication became apparent. *Risk communication* was born as a discrete field of study and practice.

What is Risk Communication?

Risk communication is a marriage of communication theory and risk studies [3]. Although rooted in these disciplines, the field of risk communication has evolved somewhat independently as a distinct area

of scientific inquiry and practice. In the last 25 years researchers and practitioners in a wide range of disciplines have developed theoretical frameworks and models to increase the effectiveness of communications about risk [3–9]. They have also sought to ease the growing tensions between the “experts” and “public” by exploring and conceptualizing the factors dealing with various reactions to and explanations of risk [10, 11].

Risk communication is now acknowledged to be “an interactive process of exchange of information and opinion among individuals”. Successful communication is defined as that which “raises the level of understanding of relevant issues or actions for those involved and satisfies them that they are adequately informed within the limits of available knowledge” [3, p. 2]. However, risk communication has not always been defined in terms of these enlightened reciprocal and inclusive concepts.

Evolution of Risk Communication

The early approaches to risk assessment and risk management generally considered communication to be the final stage of risk management, after the technical risk assessment and selection of risk-management options had been completed (Figure 1). Risk communication was originally thought of as consisting of a one-way message from experts and/or agencies to the public of technical and scientific information, with the primary purpose of persuading people to accept a decision that had already been made (Figure 2). This approach proved to be overwhelmingly unsuccessful, frequently resulting in conflict and frustration on all sides.

The turning point in the approach to risk communication occurred in the late 1980s, when risk practitioners began to reframe the issue of risk communication as a problem in communication theory and practice rather than as simply risk concepts [4]. A milestone in the evolution of current risk communication concepts and practice was the 1989 publication of *Improving Risk Communication*, by a group of committees under the National Research Council [3]. Two subsequent landmark documents in the United States on risk characterization and risk management have been extremely influential internationally in espousing the need to integrate communication and consultation throughout

Figure 1 Evolving role of risk communication in risk process models

Figure 2 Evolution of risk communication

the risk-management process. *Understanding Risk: Informing Decisions in a Democratic Society* by the US National Research Council National Academy of Science [12] and the *Framework for Environmental Health Risk Management* by the US Presidential/Congressional Commission on Risk Assessment and Risk Management [13] both strongly recommended full collaboration and communication with all interested and affected parties in the early stages of problem formulation and solution development for environmental risk problems so that public values can inform and influence the shaping of risk-management strategies. While most previous models dealt largely with communication *effects*, these models recognized that communication is a *process* that is inextricably linked to the analysis and deliberation of the subject area being communicated.

Risk communication is now generally considered to be a two-way dialogue between experts and the public to exchange all types of information, knowledge, and experience about the risk situation (Figure 2). Its primary purpose is to inform people so that they may make responsible decisions on managing risk. The main tenet of informed and effective modern-day risk communication is the right of people and communities to participate in decisions that affect their lives and those of the people they care about (*see Stakeholder Participation in Risk Management Decision Making*). Communication with interested and affected parties should start with the formulation of the risk problem and continue through the assessment and selection of appropriate risk-management strategies (Figure 1).

Table 1 Risk communication stages^(a)

“All we have to do is get the numbers right.” . . . tell them the numbers.” . . . explain what we mean by the numbers.” . . . show them that they’ve accepted similar risks in the past.” . . . show them that it’s a good deal for them.” . . . treat them nice.” . . . make them our partners.” . . . all of the above”
--

Unfortunately, not everyone has learned from the changing perspectives and approaches to risk communication and the skills that have been developed to put these concepts into practice. Many agencies and industries have felt compelled to repeat the learning process of their predecessors. Fischhoff [14] outlined eight development stages in the evolution of risk communication (Table 1). He concluded that ultimately all of the development stages are necessary for successful risk communication. We need rigorous, defensible science to conduct risk assessments. We need to present these risk estimates to the people involved, and do everything possible to ensure their understanding. We need to provide a context for this information, and to ensure that the information is balanced with respect to risks and potential benefits. And finally, we need to treat people with respect, and to involve them as full partners in the risk process to ensure that all types of information are considered.

Fischhoff further commented that, as in the biological concept that “ontogeny recapitulates phylogeny” (i.e., the development of the individual mimics the evolution of the species), risk practitioners seem bent on recreating this developmental sequence of failures for each new risk problem. His summary of risk communication evolution has resonated strongly with most risk communication practitioners because it so aptly and succinctly embodies the flawed learning progression of this discipline.

Risk Communication as an Integral Part of Risk Management

Rigorous, scientifically based risk assessment is a necessary input to the risk-management process. However, we now know (through a repeated series

of usually frustrating and painful past experiences) that more than good risk science is necessary to ensure successful, accepted risk-management decisions. Other factors (such as economic, social, cultural, ethical, political, and legal considerations) must also be incorporated in risk-management decisions [13]. Ultimately, this complex process of risk management cannot succeed without open, comprehensive, timely, and reciprocal dialogue on the risk issues. Risk communication has thus become the critical key to success for all risk-management initiatives.

However, incorporation of effective risk dialogue from the outset and throughout the risk-management process is still not being consistently achieved. Part of the problem is a lack of understanding by risk assessors and risk managers on the importance of risk communication. Equally problematic is the lack of institutional and organizational commitment to the full incorporation of risk communication in their risk processes [15]. The success of employing good risk communication practice is often measured in part by a relative lack of controversy on a risk issue. Unfortunately, this very success is often translated by organizations as no longer requiring the expenditure of time and resources to communicate because “nothing is going wrong”. When risk communication is not fully incorporated from the beginning of an issue, and the process does become contentious, organizations then (erroneously) assume that suddenly adopting risk communication procedures will resolve the problem. Both of these practices inevitably fail to achieve risk-management objectives, yet managers and organizations continue to resist committing the time and resources into incorporating risk communication as an integral part of their risk-management programs. We need to continue both to learn from

our past experiences and to apply these lessons consistently if we are to genuinely improve our dialogues on risk issues.

Ruin Probabilities: Computational Aspects

Ruin probabilities is a traditional research area within the field of collective risk theory in insurance mathematics. Since the pioneering works of Lundberg and Cramér, it has interested a number of researchers and practitioners. A large and rich literature can be found in journals devoted to actuarial sciences, probability, and statistics. The topic is developed to various degrees in the comprehensive books [1–7].

The present paper is concerned with the numerical evaluation of the ruin or nonruin probabilities, over an infinite horizon and in finite time. We focus primarily on the compound Poisson model, which is the classical model in collective risk theory. A succinct overview of related problems and models is given at the end of the article.

The list of references is nonexhaustive. The absence of reference for a specific result means that the result is standard and can be easily found in the books referred to above.

Compound Poisson Model

A risk model aims at describing and analyzing the time evolution of the reserves (or surplus) of an insurance company. It is built on the basis of two processes: the claim process, which is stochastic because the arrival of claims and their amounts are random by nature, and the premium process, which is quite often considered as deterministic because premiums are collected at a nearly known rate.

The most prominent model is the compound Poisson risk model. Its advantage is that it is mathematically rather simple and relies on intuitive grounds. The underlying assumptions are quite acceptable for many applications, but could be restrictive in some cases. This model also leads to the development of some more realistic and still tractable models.

Specifically, on the one hand, claims arrive according to a Poisson process $\{N(t)\}$ with mean $\lambda > 0$ per unit time. This assumption is natural for a large portfolio of insurance policies, all independent and each having a small probability of claim. The successive claim amounts $\{X_i\}$ are independent random variables with common distribution function

$F(x)$, with $F(0) = 0$, and independent of $\{N(t)\}$. So, claims occur according to a compound Poisson process $\{S(t)\}$ given by $S(t) = \sum_{i=1}^{N(t)} X_i$. On the other hand, the insurer has an initial surplus $u \geq 0$ and receives premiums continuously at a constant rate $c > 0$. This assumption is reasonable in practice, but extension to time-dependent rates is still possible. Combining both claim and premium processes, we see that the surplus at time t is

$$U(t) = u + ct - S(t) \quad (1)$$

Ruin (*see Ruin Theory*) occurs as soon as the surplus becomes negative or null, i.e., at time $T(u) = \inf\{t > 0 : U(t) \leq 0\}$ ($T(u) = \infty$ if ruin does not occur). In other words, $T(u)$ is the first-crossing time of the process $\{S(t)\}$ through the upper linear boundary $y = u + ct$. We denote by $\phi(u, t)$ the probability of nonruin until time t :

$$\begin{aligned} \phi(u, t) &= P[T(u) > t] \equiv P[U(\tau) \\ &= u + c\tau - S(\tau) > 0 \text{ for } 0 < \tau \leq t] \end{aligned} \quad (2)$$

$\psi(u, t) = 1 - \phi(u, t)$ is the probability of ruin before time t . As $t \rightarrow \infty$, equation (2) becomes the ultimate nonruin probability $\phi(u) = P[T(u) = \infty]$, and the ultimate ruin probability is $\psi(u) = 1 - \phi(u)$. These probabilities are the topics of interest hereafter.

Ultimate Ruin Probability

Let $\mu = E(X_1)$ denote the expected claim amount. If $c \leq \lambda\mu$, ruin is sure over infinite horizon ($\psi(u) = 1$ for any $u \geq 0$). This is not surprising since the condition means that, per unit time, the premium is at most equal to the expected aggregate claim. If, on the contrary, $c > \lambda\mu$, ultimate nonruin has a positive probability ($\phi(u) > 0$ for any $u \geq 0$, with $\phi(u) \rightarrow 1$ as $u \rightarrow \infty$). It is thus natural to assume that $c = \lambda\mu(1 + \theta)$ where $\theta > 0$ is the relative security loading.

Exact Results

To determine $\phi(u)$, a standard approach is to show that $\phi(u)$ satisfies an integro-differential equation, and this yields the following integral equation:

$$\begin{aligned} \phi(u) &= \phi(0) + \frac{\lambda}{c} \int_0^u \phi(v)[1 - F(u - v)] dv, \\ u &\geq 0 \end{aligned} \quad (3)$$

One gets from equation (3) that when $u = 0$ (no initial reserve),

$$\phi(0) = \frac{1 - \lambda\mu}{c (= \theta/(1 + \theta))} \quad (4)$$

When $u > 0$, equation (3) is called a defective renewal equation (it corresponds to a Volterra-type integral equation of the second kind). Several algorithms developed in numerical analysis permit one to obtain the numerical solution to such an equation (see, e.g., Appendix D in [6]). An alternative method is to derive from equation (3), the Laplace transform of $\phi(u)$ and then to invert it numerically (e.g. [8]).

From equation (3) one can also prove that $\phi(u)$ is the distribution function of a compound geometric distribution, i.e.,

$$\phi(u) = \left(\frac{1 - \lambda\mu}{c} \right) \sum_{i=0}^{\infty} \left(\frac{\lambda\mu}{c} \right)^i F_e^{*i}(u), \quad u \geq 0 \quad (5)$$

where $F_e^{*i}(u)$ is the i -fold convolution of a distribution function $F_e(u)$ which corresponds to the equilibrium distribution associated with $F(\cdot)$, i.e., $F_e(u) = (1/\mu) \int_0^u [1 - F(x)] dx$, $u \geq 0$. This representation of $\phi(u)$ is called the Pollaczek–Khinchine (or Beekman) formula. The result is elegant, but does not lend itself easily to numerical evaluations because of the infinite series of convolution powers in equation (5). It can simplify, however, for particular claim distributions. For example, if claims are exponentially distributed with $F(x) = 1 - e^{-x/\mu}$, $x > 0$, then $\phi(u) = 1 - (\lambda\mu/c) e^{-(1/\mu - \lambda/c)u}$, $u \geq 0$. A large class of claim laws for which formula (5) simplifies is the class of phase-type distributions. Formula (5) can also be used for estimating ruin probabilities by Monte Carlo simulation (e.g. [9]). Finally, this formula is of interest when addressing problems of a theoretical nature (such as the approximation of $\phi(u)$ for large u).

Approximations

An efficient method introduced in [10] is to first approximate the claim amount law by a discrete distribution. The successive claims are so approximated by independent discrete random variables $\{X_i\}$ with common probability mass function g_n , $n = 1, 2, \dots$. Several techniques permit arithmetizing distributions and provide, in general, a high degree of accuracy

(see, e.g., Section 6.15 in [6]). One can then prove that for discrete claims, the series given by formula (5) for $\phi(u)$ may be transformed into a simple finite sum. For clarity, choose u a nonnegative integer. Following [11], the formula is written as

$$\phi(u) = \left(\frac{1 - \lambda\mu}{c} \right) \sum_{j=0}^u h_j \left(\frac{j - u}{c} \right) \quad (6)$$

where the quantities $h_j(t)$ of argument $t \leq 0$ are pseudo-probability mass functions that can be computed using the recurrence equation (10) given below.

Approximation by moment fitting is a standard approach in statistics. The method presented in [12] consists of replacing the surplus process by another one with exponential claims of parameter $\hat{\beta}$, Poisson parameter $\hat{\lambda}$, and premium rate $\hat{c}$. The three new parameters are chosen to get the first three cumulants match, and it then suffices to apply the simple formula known for the exponential case. Although purely empirical, this procedure gives very good results in practice. An approximation method of similar nature is given in [13].

Bounds and Asymptotics

The adjustment coefficient (or Lundberg's exponent), denoted by γ , plays a central role here. Assume that the moment generating function of X_1 , i.e., $m(s) = Ee^{sX_1}$, is finite for some $s > 0$ (this implies that $P(X_1 > x)$ decreases exponentially fast). Then, γ is defined as the unique positive solution to the equation $\lambda + cs = \lambda m(s)$, if such a root exists. This equation may be easily solved numerically by applying, for instance, the Newton–Raphson method.

A fundamental result is Lundberg's inequality: $\psi(u) \leq e^{-\gamma u}$, $u \geq 0$ (the ruin probability is bounded by a decreasing exponential function, at rate γ , of the initial surplus). This upper bound is often taken into account in place of the true ruin probability (the larger the value of γ , the safer the portfolio). It can be used to find the initial surplus u , or the security loading θ , needed to keep the ruin probability below a fixed level. A refined inequality exists, as well as a similar exponential lower bound. Furthermore, the asymptotic behavior of $\psi(u)$ for large u is given by the celebrated Cramér–Lundberg approximation:

$$\psi(u) \approx Ke^{-\gamma u} \quad \text{as } u \rightarrow \infty, \\ \text{with } K = \frac{(c - \lambda\mu)}{[\lambda m'(\gamma) - c]} \quad (7)$$

where $m'(s)$ is the derivative of $m(s)$. The approximation works rather well with moderate values of u ; it becomes exact for exponentially distributed claims.

We underline that the basic assumption above is the existence of the coefficient γ . This is true with light-tailed claim amount distributions like the exponential or gamma. It is not the case with heavy-tailed distributions, like the lognormal or Pareto, which are useful laws for certain actuarial applications. Asymptotic approximations, however, can still be derived and exhibit a very different behavior of $\psi(u)$ (e.g. [14]).

Surpluses at Ruin

When ruin occurs ($T(u) < \infty$), $U[T(u)-]$ and $|U[T(u)]|$ measure the surplus just before ruin and the severity of ruin, respectively. These quantities give interesting information on what happens at ruin time. Let us suppose, for instance, that claim amounts are continuous variables with density function $p(x) = F'(x)$. We denote by $f(x, y|u)$ the defective joint density function of $U[T(u)-]$ and $|U[T(u)]|$, and by $f(x|u)$ the defective density function of $U[T(u)-]$, with $x, y > 0$.

When $u = 0$, one can prove the following key formula [15]:

$$f(x, y|0) = \left(\frac{\lambda}{c}\right) p(x+y), \quad x, y > 0 \quad (8)$$

Note that $f(x, y|0) = f(y, x|0)$, i.e., there is a symmetry between the laws of $U[T(u)-]$ and $|U[T(u)]|$. Integrating equation (8) over y , then gives $f(x|0) = (\lambda/c)[1 - F(x)]$, $x > 0$; obviously, it is also the density function of $|U[T(u)]|$ at point x .

When $u > 0$, it is easily seen that $f(x, y|u) = f(x|u) p(x+y)/[1 - F(x)]$, $x, y > 0$. One can then establish another key formula [16]:

$$f(x|u) = f(x|0) \frac{[\psi(u-x) - \psi(u)]}{[1 - \psi(0)]}, \quad x > 0 \quad (9)$$

where $\psi(\cdot)$ is the ultimate ruin probability, with the convention $\psi(u-x) = 1$ if $u < x$. All these results can be unified and extended through the study of an expected discounted penalty owing to ruin [17].

Finite-Time Ruin Probability

In this section, we consider again discrete claim amounts $\{X_i\}$ with probability mass function g_n , $n = 1, 2, \dots$. Continuous claims may also be discussed but, as already indicated, they are usually discretized for numerical calculations. For simplicity, u is a nonnegative integer.

We present two explicit formulae for $\phi(u, t)$. First, denote the probability mass function of $S(t)$ by $h_n(t)$, $n = 0, 1, 2, \dots$. Since $S(t)$ is of compound Poisson law, an easy way to compute $h_n(t)$ is to apply Panjer's recursion formula, which gives

$$h_0(t) = e^{-\lambda t}, \quad \text{and} \quad h_n(t) = \frac{\lambda t}{n} \sum_{j=1}^n j g_j h_{n-j}(t), \quad n = 1, 2, \dots \quad (10)$$

Note that the relation (10) may be written for any real t , positive or not. If $t < 0$, $\{h_n(t)\}$ corresponds to a pseudo-probability mass function (with no practical interpretation).

Now, when $u = 0$, a classical ballot theorem yields for $\phi(0, t)$ the Takàcs formula:

$$\phi(0, t) = \frac{1}{ct} \sum_{j=0}^{[ct]} (ct - j) h_j(t) \quad (11)$$

where $[x]$ is the integer part of x .

When $u > 0$, a simple probabilistic argument leads to the Seal formula for $\phi(u, t)$: if $ct \leq 1$, $\phi(u, t) = \sum_{j=0}^u h_j(t)$, and if $ct > 1$,

$$\begin{aligned} \phi(u, t) &= \sum_{j=0}^{u+[ct]} h_j(t) - \sum_{j=1}^{[ct]} h_{u+j} \left(\frac{j}{c}\right) \\ &\quad \times \phi\left(0, \frac{ct-j}{c}\right) \end{aligned} \quad (12)$$

An alternative approach proposed recently [11, 18] has recourse to the functions $h_n(t)$ defined for any real t . This permits one to obtain for $\phi(u, t)$ the Picard-Lefèvre formula:

$$\begin{aligned} \phi(u, t) &= \sum_{j=0}^u \left\{ h_j(t) + h_j \left(\frac{j-u}{c}\right) \sum_{n=u+1}^{u+[ct]} \right. \\ &\quad \times \left. \frac{u+ct-n}{u+ct-j} h_{n-j} \left(\frac{u+ct-j}{c}\right) \right\} \end{aligned} \quad (13)$$

Note that $(j - u)/c \leq 0$ in $h_j(\cdot)$ above. Formula (13) reduces to result (11) if $u = 0$ and becomes result (6) as $t \rightarrow \infty$. Numerical comparisons between formulae (12) and (13) show that formula (12) is well adapted when $u \gg ct$, while formula (13) is preferable when $u \ll ct$ [19].

Working with discrete claims is quite convenient because ruin can occur only at levels $u + 1, u + 2, \dots$, and the only possible ruin times are thus $1/c, 2/c, \dots$. Over a horizon $(0, t)$, it then suffices to examine the times j/c , $j = 1, \dots, [ct]$, and time t , which yields $\phi(u, t) = P\{S(j/c) < u + j, j = 1, \dots, [ct], S(t) < u + [ct] + 1\}$. When the premium income is arbitrary, adapting this reasoning permits the construction of a recursive method for $\phi(u, t)$, either directly [19] or by using the generalized Appell (or Sheffer) polynomials (e.g. [11]). Extensions are also possible to multirisks [20] and to interdependent claims (e.g. [21]).

Finally, we refer the reader to two approximation methods using a discrete-time scale [22, 23].

Related Problems and Models

The economic context can require incorporating additional factors in the model. Various extensions that can be taken into account are as follows: an arbitrary premium income, inhomogeneous claim amounts, premiums depending on the reserves, a fixed or random discount factor, a dividend barrier, interdependent claim amounts, dependence between arrival times and claim amounts, multiple risks or a Markovian environment.

The compound Poisson model itself can be questioned. Several variants often proposed are as follows: the compound binomial model (discrete-time analog of the model), the renewal Sparre–Andersen model (independent interclaim periods with arbitrary common law), and the compound Poisson model perturbed by a Brownian motion or an α -stable Lévy motion.

CLAUDE LEFÈVRE

Ruin Theory

Ruin theory examines the solvency of an insurer in a theoretical setting. The insurer's surplus or reserve for an insurance portfolio over time is modeled by a stochastic process. Of central importance in the evaluation of the surplus are the time of ruin at which the surplus becomes negative for the first time, the surplus immediately before the time of ruin, and the deficit at the time of ruin. The use of stochastic processes for modeling the surplus of an insurer can be dated back to 1909, when Lundberg presented his paper "On the theory of risk" at the Sixth International Congress of Actuaries (see [1]). In his paper, the surplus was described by a shifted compound Poisson process. The compound Poisson surplus process was further investigated by Cramér (see [2]) and is a topic of interest even today. This process has been extended and generalized in several directions. Interest rates are incorporated into surplus processes. The claim arrivals are assumed to follow a more general counting process than a Poisson process. Further, the fluctuation of the surplus is considered and modeled by a Brownian motion, and more generally by a diffusion process. Also considered are surplus processes with dividend policies are also considered.

The Compound Poisson Surplus Process

The compound Poisson surplus process can be described as follows: The Poisson process $N(t)$ with intensity λ representing the number of claims experienced by the insurance portfolio over time. More precisely, the number of claims over the time period $[0, t]$ is $N(t)$. The amount of the i th claim is represented by the random variable Y_i . Hence, the aggregate claims arising from the insurance portfolio over the time period $[0, t]$ is given by

$$S(t) = Y_1 + Y_2 + \cdots + Y_{N(t)} \quad (1)$$

with the convention that $S(t) = 0$ if $N(t) = 0$. It is assumed that these individual claim amounts $Y_1, Y_2, \dots$, are positive, independent and identically distributed with a common distribution function $P(x)$, and that they are independent of the number of claims processed $N(t)$. Thus, the aggregate claims

processed $\{S(t)\}$ is a compound Poisson process. As shown in *collective risk models* (see **Collective Risk Models**), the mean and the variance of $S(t)$ are $E\{S(t)\} = \lambda p_1 t$ and $\text{Var}\{S(t)\} = \lambda p_2 t$, where p_1 and p_2 are the first two moments about the origin of Y , a representative of the claim amounts Y_i 's. Suppose that the insurer has an initial surplus $u \geq 0$ and receives premiums continuously at the rate c per unit time. The insurer's surplus process is then given by

$$U(t) = u + ct - S(t) \quad (2)$$

The surplus process (2) is referred to as the *classical compound Poisson surplus process*. It is normally assumed that the insurer charges a risk premium and in this case, the premium rate c will exceed the expected aggregate claims per unit time, i.e., $c > E\{S(1)\} = \lambda p_1$. Let $\theta = [c - E\{S(1)\}]/E\{S(1)\} > 0$. Then one has $c = \lambda p_1(1 + \theta)$. The parameter θ is called the *relative security loading* (see **Ruin Probabilities: Computational Aspects**).

The time of ruin is given by $T = \inf\{t; U(t) < 0\}$ the first time the surplus becomes negative. The first quantity under consideration is the probability that ruin occurs in finite time, i.e., $\psi(u) = \Pr\{T < \infty\}$, the probability of ruin. With the independent increments property of the Poisson process, it can be shown that the probability of ruin $\psi(u)$ satisfies the defective renewal equation (see **Reliability Growth Testing**)

$$\begin{aligned} \psi(u) = & \frac{1}{1 + \theta} \int_0^u \psi(u - x) dP_1(x) \\ & + \frac{1}{1 + \theta} [1 - P_1(u)] \end{aligned} \quad (3)$$

where $P_1(x)$ is the equilibrium distribution function of $P(x)$ and is given by $P_1'(x) = [1 - P(x)]/p_1$. Since the probability of ruin $\psi(u)$ is the solution of the defective renewal equation (3), methods for renewal equations are applicable. The key renewal theorem (see [3]) implies that

$$\psi(u) \sim \frac{\theta p_1}{E\{Xe^{\kappa X}\} - (1 + \theta)p_1} e^{-\kappa u}, \quad \text{as } u \rightarrow \infty \quad (4)$$

where the parameter κ is the smallest positive solution of

$$\int_0^\infty e^{\kappa x} dP_1(x) = 1 + \theta \quad (5)$$

and $a(u) \sim b(u)$ means $\lim_{u \rightarrow \infty} a(u)/b(u) = 1$. The parameter κ is called the *Lundberg adjustment coefficient* in ruin theory and it plays a central role in analysis of not only the probability of ruin but also other important quantities in ruin theory. With the Lundberg adjustment coefficient κ , we can also obtain a simple exponential upper bound, called the *Lundberg bound*, for the probability of ruin:

$$\psi(u) \leq e^{-\kappa u}, \quad u \geq 0 \quad (6)$$

The defective renewal equation (3) also implies that $\psi(u)$ is the survival probability of a compound geometric distribution, where the geometric distribution has the probability mass function

$$\frac{\theta}{1+\theta} \left(\frac{1}{1+\theta} \right)^n, \quad n = 0, 1, \dots$$

and the secondary distribution is $P_1(x)$. This compound geometric representation enables us to obtain an analytical solution for $\psi(u)$. It is easy to see that

$$\psi(u) = \sum_{n=1}^{\infty} \frac{\theta}{1+\theta} \left(\frac{1}{1+\theta} \right)^n [1 - P_1^{*n}(u)], \quad u \geq 0 \quad (7)$$

where $P_1^{*n}(u)$ is the n -fold convolution of P_1 with itself. The formula (7) is often referred to as *Beekman's convolution formula* in actuarial science (see [4]) and the use of the formula can be found in [5, 6]. A disadvantage of the formula is that it involves an infinite number of convolutions, which can be difficult to compute in practice.

In some situations, a closed form solution for $\psi(u)$ can be obtained. When the individual claim amount distribution $P(x)$ is a combination of exponential distributions, i.e.,

$$P'(x) = \sum_{j=1}^m q_j \mu_j e^{-\mu_j x} \quad (8)$$

where $0 < \mu_1 < \mu_2 < \dots < \mu_m$ and $\sum_{j=1}^m q_j = 1$, then

$$\psi(u) = \sum_{j=1}^m C_j e^{-R_j u} \quad (9)$$

where R_j 's are the positive solutions of the Lundberg equation (5) and

$$C_j = \frac{\left\{ \sum_{i=1}^m \frac{q_i}{\mu_i - R_j} \right\}}{\left\{ \sum_{i=1}^m \frac{q_i \mu_i}{(\mu_i - R_j)^2} \right\}} \quad (10)$$

For further details see [7] and [8].

When the individual claim amount distribution $P(x)$ is a mixture of Erlang distributions, i.e.,

$$P'(x) = \sum_{j=1}^m q_j \frac{\mu^j x^{j-1} e^{-\mu x}}{(j-1)!} \quad (11)$$

where $\mu > 0$, $q_j \geq 0$, $j = 1, 2, \dots, m$ and $\sum_{j=1}^m q_j = 1$,

$$\psi(u) = e^{-\mu u} \sum_{j=0}^{\infty} C_j \frac{[\mu u]^j}{j!} \quad (12)$$

where the coefficients C_j 's are obtained by a recursive formula that can be found in [9]. An analytical expression is also available for more general phase-type individual claim amount distributions. However, its calculation is not as straightforward and requires the use of the matrix-analytic method (see [10] for details).

The classical results discussed above may be found in many books on risk theory, including [11–15].

The Expected Discounted Penalty Function

Further investigation of the surplus process involves the surplus immediately before the time of ruin $U(T-)$ and the deficit at the time of ruin $|U(T)|$. Dickson studied the joint distribution of $U(T-)$ and $|U(T)|$ in [16]. The expected discounted penalty function introduced by Gerber and Shiu in the seminal paper [17] is very useful for analysis of T , $U(T-)$, and $|U(T)|$ in a unified manner. The expected discounted penalty function is defined as

$$\phi(u) = E \left\{ e^{-\delta T} w(U(T-), |U(T)|) I(T < \infty) \right\} \quad (13)$$

where $w(x, y)$ is the penalty when the surplus immediately before the time of ruin is x and the deficit at

the time of ruin is y . Note that $I(A)$ is the indicator function of event A , and the parameter δ is the interest rate compounded continuously. Many quantities of interest may be obtained by choosing a proper penalty function $w(x, y)$. For example, when $w(x, y) = 1$, we obtain the Laplace transform of T where δ is the variable of the transform. If $w(x, y) = I(x \leq u, y \leq v)$ for fixed u and v , and $\delta = 0$, we obtain the joint distribution function of $U(T-)$ and $|U(T)|$. Furthermore, if $w(x, y) = x^k y^l$ and $\delta = 0$, the joint moments of $U(T-)$ and $|U(T)|$ are obtained.

It is shown in [17] that the expected discounted penalty function $\phi(u)$ satisfies the defective renewal equation

$$\begin{aligned} \phi(u) = & \int_0^u \phi(u-x)g(x) dx \\ & + \frac{\lambda}{c} e^{\rho u} \int_u^\infty e^{-\rho x} \int_x^\infty w(x, y-x) \\ & \times dP(y) dx \end{aligned} \quad (14)$$

where ρ is the unique nonnegative solution to the Lundberg equation

$$c\xi + \lambda\tilde{p}(\xi) - (\lambda + \delta) = 0 \quad (15)$$

and the kernel density $g(x)$ is given by

$$g(x) = \frac{\lambda}{c} \int_x^\infty e^{-\rho(y-x)} dP(y) \quad (16)$$

This result is of great significance as it allows for the utilization of the theory of renewal equations to analyze the expected discounted penalty function $\phi(u)$. For example, it can be shown that the Laplace transform of T is a survival probability of a compound geometric distribution. Moreover, the general expected discounted penalty function can be expressed in terms of the Laplace transform. As a result, many analytical properties of the expected discounted penalty function may be obtained (see [9, 17–19]).

The Compound Poisson Surplus Process with Interest Rate

The classical compound Poisson surplus process assumes that the surplus receives no interest over time. The compound Poisson surplus process with

constant interest rate was first studied in [20] and the model was further considered in [21–25]. They mainly focus on the probability of ruin. It is assumed that the insurer receives interest on the surplus at constant rate δ , compounded continuously. Thus, the surplus at time t can be expressed as

$$U(t) = ue^{\delta t} + c \frac{e^{\delta t} - 1}{\delta} - \int_0^t e^{\delta(t-s)} dS(s) \quad (17)$$

Sundt and Teugels [24] show that the probability of ruin $\psi(u)$ satisfies the integral equation

$$\begin{aligned} [c + \delta u]\psi(u) = & \int_0^u \psi(u-x) \\ & \times [\delta + \lambda(1 - P(x))] dx \\ & + \lambda \int_u^\infty (1 - P(x)) dx - \frac{\theta - \theta'}{1 + \theta'} \lambda p_1 \end{aligned} \quad (18)$$

where $\theta' < \theta$ is given in [24]. The equation (18) is nonlinear and hence is, in general, not solvable. However, an analytical solution exists for the exponential individual claims (see again [24]).

Recently, the expected discounted penalty function under the above model and with stochastic interest rates have been considered (see [26–28] and references therein).

The Compound Poisson Surplus Process with Diffusion

Dufresne and Gerber [29] first considered the compound Poisson surplus process perturbed by diffusion and assumed the surplus process is given by

$$U(t) = u + ct - S(t) + \sigma W(t) \quad (19)$$

where $\{W(t)\}$ is the standard Brownian motion and $\sigma > 0$. The diffusion (*see Role of Alternative Assets in Portfolio Construction; Default Risk*) term $\sigma W(t)$ may be interpreted as the additional uncertainty of the aggregate claims, the uncertainty of the premium income, or the fluctuation of the investment of the surplus, where σ is the volatility. In this

situation, the expected discounted penalty function needs to be modified. Let

$$\phi_d(u) = E \left\{ e^{-\delta T} I(T < \infty, U(T) = 0) \right\} \quad (20)$$

and

$$\begin{aligned} \phi_s(u) = E \left\{ e^{-\delta T} w(U(T-), |U(T)|) \right. \\ \left. I(T < \infty, U(T) < 0) \right\} \end{aligned} \quad (21)$$

The expected discounted penalty function is defined as

$$\phi(u) = w_0 \phi_d(u) + \phi_s(u) \quad (22)$$

The first term represents the penalty caused by diffusion and the penalty is w_0 , and the second term represents the penalty caused by an insurance claim. It is shown in [30] that the expected discounted penalties $\phi_d(u)$ and $\phi_s(u)$ satisfy the second-order integro-differential equations:

$$\begin{aligned} D\phi_d''(u) + c\phi_d'(u) + \lambda \int_0^u \phi_d(u-y) dP(y) \\ - (\lambda + \delta)\phi_d(u) = 0 \end{aligned} \quad (23)$$

$$\begin{aligned} D\phi_s''(u) + c\phi_s'(u) + \lambda \int_0^u \phi_s(u-y) dP(y) \\ + \lambda \int_u^\infty w(y, y-u) dP(y) \\ - (\lambda + \delta)\phi_s(u) = 0 \end{aligned} \quad (24)$$

where $D = \sigma^2/2$. Similar to the classical compound Poisson case, it has the Lundberg equation

$$D\xi^2 + c\xi + \lambda\tilde{p}(\xi) - (\lambda + \delta) = 0 \quad (25)$$

which has a nonnegative root ρ . The expected discounted penalty function $\phi(u)$ satisfies a defective renewal equation with the kernel density

$$g(x) = \frac{\lambda}{D} \int_0^x e^{-d(x-v)} \int_v^\infty e^{-\rho(y-v)} dP(y) \quad (26)$$

and $d = c/D + \rho$. An interesting finding is that the probability of ruin, as a special case, is a convolution of an exponential density with the tail of a compound geometric distribution (see [29]).

The compound Poisson process with diffusion equation (19) is a special case of Lévy processes and hence it is natural to consider a class of Lévy

processes for the surplus process that have only negative jumps. A number of papers discuss the probability of ruin for this class of surplus processes (see [31–33]). More recently, the expected discounted penalty function for general Lévy processes have been investigated in [34]. Generally, the results for Lévy surplus processes are very similar to those for the compound Poisson process with diffusion.

The Sparre Andersen Surplus Process

The compound Poisson surplus process implicitly assumes that the interclaim times are independently and identically exponentially distributed. A more general model involves the assumption that the interclaim times are independent and identically distributed, but not necessarily exponential. The resulting surplus process is referred to as a *renewal risk process*, or as a *Sparre Andersen process* after its usage was proposed in [35].

Analysis of the Sparre Andersen surplus process is more difficult than the compound Poisson special case, but some progress has been made. Because the process is regenerative at claim instants, it can be shown that the ruin probability is still a compound geometric tail. In fact, the expected discounted penalty function defined by equation (13) still satisfies a defective renewal equation, and the Laplace transform of the ruin time T is still a compound geometric tail. The defective renewal equation structure implies that Lundberg asymptotics and bounds hold in this more general situation. For further discussion of these issues, see [36–38] and references therein.

The difficulty with the use of this model, in general, is the fact that it is difficult to identify the geometric parameter and the ladder height (or geometric secondary) distribution. This is true even for the special case involving the ruin probabilities. Such identification normally requires that further assumptions be made about the interclaim time distribution and/or the claim size distribution. In [39], Dickson and Hipp considered Erlang(2) interclaim times, whereas Gerber and Shiu [36] and Li and Garrido [40] considered the Erlang(n) case. Also, Li and Garrido [37] considered the much more general case involving Coxian interclaims. Conversely, parametric assumptions about claim sizes rather than interclaim times were considered by Willmot [38]. The situation with phase-type assumptions is discussed in [10].

A closely related model is the delayed Sparre Andersen model where the time until the first claim is independent, but not distributed as the subsequent interclaim times. This model attempts to address the criticism that the Sparre Andersen model implicitly assumes that a claim occurs at time zero. Other classes of surplus processes that do not have stationary and independent increments are the nonhomogeneous Poisson process, the mixed Poisson process, and more generally, Cox processes. Similar to the renewal surplus process case, analysis of these processes is also difficult. For further details on the Sparre Andersen and related processes, see [10, 15, 41, 42] and references therein.

Dividend Strategies

As mentioned earlier, an insurer normally charges a risk premium on its policies, which implies that the premium incomes are greater than the expected aggregate claims. In this case, the probability of ruin is less than one. Hence, there is a positive probability that the surplus will grow indefinitely, an obvious shortcoming of the aforementioned surplus processes. To overcome this shortcoming, De Finetti in [43] suggested that a constant dividend barrier be imposed so that the overflow of the premium incomes is paid as dividends (the constant dividend barrier was originally applied to a binomial surplus process in his paper). This dividend strategy is usually referred to as the *constant barrier dividend Strategy*. Early studies on this strategy can be found in [11, 13, 44, 45]. A generalization of the constant barrier dividend strategy is the threshold dividend strategy under which a fixed proportion of the premiums is paid as dividends when the surplus is above the constant barrier. The threshold dividend strategy can also be viewed as a two-step premium as described in [10].

The research on surplus processes with dividend strategies is primarily concerned with (a) calculation of the expected discounted total dividends and identification of optimal dividend strategies and (b) the expected discounted penalty function. When the surplus process is compound Poisson, the expected discounted total dividends satisfies a homogeneous piecewise first-order integro-differential equation, and hence is solvable. The result also holds for the

Lévy surplus process except that the equation is of second order. When the objective is to maximize the expected discounted total dividends with no constraints, the optimal dividend strategy for the compound Poisson surplus process is the constant barrier dividend strategy if the individual claims follow an exponential distribution and the so-called band strategy for an arbitrary individual claim distribution. If an upper bound is imposed for the dividend rate, then the threshold dividend strategy is optimal for the compound Poisson surplus process with the exponential individual claim distribution. It is generally believed that these results also hold for general Lévy processes, but they have not been proved; see [11, 46] and references therein. Other objectives may be used for choosing an optimal constant barrier. Dickson and Waters [47] consider the maximization of the difference between the expected discounted total dividends and the expected discounted deficit at the time of ruin. It was extended to maximize the difference between the expected discounted total dividends and the expected discounted penalty in [48].

There has been renewed interest in studying the time of ruin and related quantities for surplus processes with dividend policies in recent years, especially since the introduction of the expected discounted penalty function in [17]. The probability of ruin is given in [10] for the compound Poisson surplus. It is shown in [49, 50] that the expected discounted penalty function satisfies a nonhomogeneous piecewise first-order integro-differential equation, and hence is solvable in many situations. Some related papers on this problem include [51, 52]. An interesting result among others (see [50]) is the dividends-penalty identity that states that the increment in the expected discounted penalty owing to the constant barrier strategy is proportional to the expected discounted total dividends. This result has been extended to the stationary Markov surplus process in [48]. Other extensions include nonconstant barriers and multiple constant barriers (see [53–57] and references therein). There are a number of papers considering the renewal surplus process with a constant dividend barrier; see [58], for example. However, a constant dividend barrier is less interesting as it can not provide an optimal dividend strategy owing to the nonstationarity of the claim arrivals.

Safety

Patient safety is of primary importance; safety must be ensured throughout the clinical trials (*see* **Randomized Controlled Trials**) that are conducted during the process of developing a new drug (intervention) and maintained after the drug is approved for use. Once a drug is approved for marketing, the safety data that are available provide patients and physicians with the ability to assess safety risks relative to efficacy benefits.

The safety assessment takes on different forms that depend on the various phases of the development program (phases I–IV) and continues through surveillance of marketed drugs. In preclinical animal studies (*see* **Cancer Risk Evaluation from Animal Studies**) and in early Phase I studies, we examine the absorption, excretion, dose ranging, tolerance, and other pharmacokinetics measures in humans [1]. In phase I dose finding studies, dose limiting toxicities are identified and the maximum tolerated dose as well as the recommended phase II dose are identified on the basis of the dose escalation scheme and expected and unexpected toxicities that occur during the process. The safety assessments in phase II and III trials include ongoing monitoring of adverse events (AEs) and serious adverse events (SAEs). (*See* **Toxicity (Adverse Events)**.)

Safety is assessed at the individual patient level, the trial level, and across trials. AEs are defined, as such, if they arise for the first time during treatment, or, if they increase in severity during treatment (if they are present prior to the start of treatment). AEs that occur to an individual patient are recorded and reviewed; SAEs are reported to regulatory agencies and study sponsors; and the toxicity profile within a patient is reviewed. The patient level AE review focuses on severity, drug causality, drug relatedness, and resolution of the AE. At the trial level, this review includes summaries of the proportion of patients on the drug with specified AEs (including severity and/or drug relatedness). Summaries can be grouped by types of abnormalities in laboratory measurements, and by anatomy (body system) and/or pathophysiology (changes in body function caused by disease). Trends or patterns of AEs in subgroups of patients (e.g., gender, age, and ethnicity subgroups) can also be identified. The experimental group can be compared to the control group in phase III by

examining the time to the first occurrence of specified AEs (using Kaplan–Meier curves), and by estimating *relative risks* (*see* **Relative Risk**), *odds ratios* (*see* **Odds and Odds Ratio**), and *hazard ratios* (*see* **Hazard and Hazard Ratio**). Safety data can be combined across clinical trials using techniques of meta-analysis (*see* **Meta-Analysis in Clinical Risk Assessment**).

In some phase II trials, and in all phase III randomized clinical trials, an independent data safety and monitoring committee (DSMC) monitors the ongoing trial for safety (as described above), and, if planned, for efficacy. See [2, 3] for discussion of DSMC roles.

Once a drug is approved, postmarketing (phase IV) trials are conducted to study additional indications, new dosing regimens, or new formulations. These trials are similar to phase III trials both in conduct and monitoring. In addition to the safety data captured in phase IV trials, all serious, unexpected AEs that occur in the general population that uses the drug must be reported to the sponsor and to regulatory agencies. New or unexpected serious AEs, which are rare, can usually be detected only in postmarketing phase when relatively large numbers of patients use the drug compared to the numbers treated in clinical trials.

One should note, however, that assessment of safety when a drug is widely used is difficult because patient and physician AE reports are *ad hoc* (spontaneous), and the extent of drug usage in the population is usually unknown. Often, once a drug is available, anecdotal evidence and spontaneous reports lead to the perception that usage is associated with an unexpected safety problem. Such perception can lead to a reanalysis of the clinical trial data, additional clinical trials for safety, review of regulatory spontaneous reporting databases, or active surveillance programs.

Various statistical approaches to the identification of potential safety issues (risks) have been proposed using routine databases such as the US food and drug administration (FDA) spontaneous reporting system. For example, Bayesian data mining has been proposed to identify compounds or classes of compounds with safety risks [4–7].

One should note that active postmarketing surveillance can be planned *a priori* or when potential safety issues are identified during drug development. For example, active surveillance is often planned for vaccines that are generally given to healthy subjects, and in many cases to children [8].

LEVINSON

Sampling and Inspection for Monitoring Threats to Homeland Security

Since the events of September 11, 2001, there has been increased emphasis on monitoring and surveillance to detect and prevent further terrorist attacks. While significant resources have been devoted to the *mechanics* of screening (e.g., improved X-ray equipment, chemical “sniffers”), considerably less attention has been paid to quantifying the efficacy of these surveillance programs.

Given the high volumes of passengers, containers, mail items, and various other inter and intracontinental “movements” an important consideration is the identification of a level of inspection that balances cost, inconvenience, detection success, and probability of “false triggering”. From a statistical perspective, the answer is partly provided by the theory and methods of statistical process control (SPC) and elementary probability theory. However, bio-surveillance, syndromic surveillance (*see Syndromic Surveillance*), and counterterrorism surveillance (*see Managing Infrastructure Reliability, Safety, and Security; Game Theoretic Methods; Public Health Surveillance*) are fundamentally different from monitoring activities for quality assurance in an industrial manufacturing process. Unlike the industrial setting, where there is generally good information on the performance of the manufacturing process (e.g., percent defective, proportion of nonconforming or “out-of-spec” items), monitoring in the context of bio/homeland security is characterized by extreme uncertainty. For example, because of the nefarious activities of terrorist organizations, security and intelligence organizations do not always know what it is they are looking for. As terrorists become increasingly sophisticated in their modes of attack, our uncertainty in both the likelihood of an attack and which sentinels to monitor increases. Furthermore, considerations of cost and logistics mean that we could never hope to reduce the likelihood or probabilities of such events to zero.

Given both these constraints and uncertainties, one is thus faced with the problem of how best to sample and inspect objects that potentially represent a threat to homeland security ([1] and references therein).

These objects could be, for example, containers entering shipping ports with concealed threats such as biological agents, radioactive material or weapons [2]; water reservoirs with threats of contamination; or aircraft with bombs and/or terrorists on board.

Various techniques can be used to model risks and uncertainty [3–5] associated with homeland security, including classical max–min theories, worst-case scenarios (*see Premium Calculation and Insurance Pricing; Risk Measures and Economic Capital for (Re)insurers*), expert opinion (*see Risk in Credit Granting and Lending Decisions: Credit Scoring; Operational Risk Modeling; Reliability Demonstration*), and Bayesian [6] methods (*see Repair, Inspection, and Replacement Models; Imprecise Reliability; Lifetime Models and Risk Assessment; Bayesian Statistics in Quantitative Risk Assessment*). More recently, Information Gap decision theory has been applied to monitoring for homeland security [1, 7, 8].

We present here a simple model for sampling and inspecting generic “objects” to detect threats to homeland security. The model yields rules of thumb that could be used by decision makers to set (upper) limits on the number of objects to be inspected for a given or desired level of risk, or to estimate levels or limitations to risk as a function of the number of objects inspected. The approach can be generalized in various ways, for example, to take account of imperfect detection rates [9] and several monitoring protocols [10] when the underlying probabilities of threats are subject to info-gap uncertainty.

A Model for Sampling and Inspection

Suppose that there are N objects entering an inspection point (e.g., a container port) over a time period of t units (e.g., t weeks), and that n of these objects are sampled and inspected for a particular threat T .

Define p to be the probability that an object contains a T and θ to be the probability that a T is detected if one is present. Assuming that there are no clustering effects or serial correlations, the probability that precisely k of those objects inspected contain a T and are detected, and that the remaining $N - k$ objects contain no T is $(p\theta)^k(1 - p)^{N-k}$. Multiplying this expression by $\binom{n}{k}$, the number of ways of choosing k from n , and summing over $k = 0, 1, \dots, n$ gives an expression for the probability that

no T passes undetected over some time period t . The compliment of this probability, *viz.*,

$$P_N(n, t) = 1 - [1 - p(1 - \theta)]^n [1 - p]^{N-n} \quad (1)$$

is then the probability that at least one T passes through the inspection point undetected in time t .

Ideally, one would like to minimize $P_N(n, t)$, which is easily seen from equation (1) to occur when $n = N$, i.e., when every object is inspected – which is obvious, although not achievable in practice. Furthermore, since N and n are increasing functions of time t , it follows from equation (1) that $P_N(n, t)$ approaches unity for large t except when $\theta = 1$ and $n = N$. In other words, regardless of the precise values of p , θ , n , and N (except $\theta = 1$ and $n = N$), at least one threat T will eventually pass through the inspection point undetected. To limit risks to homeland security, for example, by imposing a (small) upper bound on $P_N(n, t)$, it is thus clear that one must impose limits on import volumes (N) over specified time periods (t). For example, if we require

$$P_N(n, t) \leq \pi_c \ll 1 \quad (2)$$

with π_c some specified small number, we deduce from equations (1) and (2), by rearranging equation (1), and taking logarithms that

$$n \log \left(1 + \frac{p\theta}{1-p} \right) + N \log(1-p) \geq \log(1-\pi_c) \quad (3)$$

Assuming $p \ll 1$ (and $\pi_c \ll 1$), we can use the linear approximation $\log(1+x) \approx x$ ($|x| \ll 1$) to rewrite equation (3) as

$$N \leq \frac{\pi_c}{p(1-f\theta)} \quad (4)$$

where

$$f = \frac{n}{N} \quad (5)$$

is the inspection fraction which we assume, for illustrative purposes, to be a constant.

It follows from equation (4) that the import volume has a finite upper bound except, as noted, when $f = \theta = 1$. In practice, of course, $\theta < 1$ so that regardless of the precise values of π_c , p , θ , and f , equation (4) implies that limits must be imposed on import volumes if one wishes to reduce the chance

of threats passing inspection points undetected [2]. It is also clear from equation (4) that if one wishes to increase the upper limit on N for given π_c , or equivalently, decrease the lower limit on π_c for given N , one should choose the largest possible value of the inspection fraction f in equation (5) that is consistent with economic and other constraints. The problem, of course, is that precise values for these limits depend on p and θ which are themselves unknown and uncertain. Nevertheless, equation (4) provides a simple rule of thumb that decision makers could use in practice, using, for example, what-if or worst-case scenario estimates for p and θ .

As an example, suppose that economic constraints limit inspection fractions to 75%, and worst-case estimates are $p = 10^{-4}$ and $\theta = 2/3$. For this scenario, equation (4) gives

$$N \leq \sim 2\pi_c \times 10^{+4} \quad (6)$$

Thus, if we require $\pi_c = 10^{-2}$, say, then equation (6) implies $N \leq 200$; this presumably would impose severe restrictions on the (unit) time period over which one satisfies the likelihood constraint of equation (2). Similarly, if say, 1000 objects pass through an inspection point every month, the condition imposed by equation (2) is only achievable over a 2-month period ($N = 2000$) when $\pi_c \geq 1/10$. In other words, in this scenario over a 2-month time frame, one can only be assured that there is not more than a 1 in 10 chance of at least one threat passing undetected.

Discussion

In this article, we have presented a simple model for sampling and inspection of objects for threats to homeland security. An important general conclusion is that unless one inspects every object entering an inspection point, and unless one has perfect detection rates, at least one threat will eventually pass through the inspection point undetected. We thus need to impose limits on import volumes and periods to limit the chances of threats passing undetected. The simple model presented here can be generalized and extended in various ways by using info-gap decision theory [7] to model uncertainties in the underlying probabilities of threats being present and detected in import objects [1]. In info-gap terminology, the inequality represented by equation (2) is only one

of many possible performance requirements that decision makers may consider in arriving at so-called robust-optimal solutions [1] in which there are trade-offs between desired levels of performance and immunity to uncertainty [7]. Generalized info-gap models for homeland security are the subject of ongoing research [9, 10].

Scenario Simulation Method for Risk Management

In financial risk management, two types of risk measurements are commonly used. The first type measures the sensitivities of portfolio value to some particular market variables. Usually, a portfolio's risk profile can be described by a large number of those sensitivities. Examples include delta, gamma, and vega (*see Risk-Neutral Pricing: Importance and Relevance; Weather Derivatives; Default Risk; Statistical Arbitrage*) in options portfolios, or duration and convexity (*see Asset-Liability Management for Life Insurers*) in bond portfolios.^a The second type is more comprehensive as it calculates the probability distribution of the portfolio value at a given horizon. This then provides common risk measures that summarize the portfolio risk, such as the widely used value at risk (VaR) (*see Risk Measures and Economic Capital for (Re)insurers; Credit Scoring via Altman Z-Score; Compliance with Treatment Allocation*), defined as the maximum loss from an adverse market movement with a specified probability over a period of time.

Among the commonly applied methods to estimate VaR, the simplest is "delta approximation" (*see Simulation in Risk Management*). The method, however, critically depends on two assumptions: the normality assumption of portfolio value, and the linearity assumption of the relationship between transactions' prices and market variables. For most portfolios, especially for portfolios with options and/or embedded options (*see Options and Guarantees in Life Insurance; From Basel II to Solvency II – Risk Management in the Insurance Sector*), Monte Carlo simulation (*see Simulation in Risk Management; Structured Products and Hybrid Securities; Reliability Optimization; Uncertainty Analysis and Dependence Modeling*) is a more appropriate method. The difficulty with the Monte Carlo approach is its computational burden. To obtain a reliable estimate, the sample size has to be large. Since each sample requires a repricing of the entire portfolio, the required large

sample size often makes the Monte Carlo approach impractical.

The scenario simulation method (*see Scenario-Based Risk Management and Simulation Optimization*) described here is a computationally efficient alternative to conventional Monte Carlo for multicurrency fixed-income portfolios. Following [1], the model approximates a multidimensional lognormal distribution of interest rates and exchange rates by a multinomial distribution of key factors. While it allows very large samples of correlated yield-curve (*see Structured Products and Hybrid Securities; Credit Migration Matrices*) joint scenarios, the number of scenarios in each currency is limited, which implies that the number of portfolio evaluations is limited.

Scenario simulation provides the entire distribution of future portfolio returns (see Figures 6 and 7). From this, not only VaR, but standard deviation and other measures of risk, such as the "coherent measures of risk" of Artzner *et al.* [2], can be computed. The scenario simulation model can be applied in estimating a portfolio's overall risk profile of joint market and credit risks. In addition, scenario simulation is better suited than traditional Monte Carlo to implementing stress tests.

We present the model in two stages: single currency scenario simulation and multicurrency scenario simulation, and then discuss its applications in risk management.

Single Currency Scenario Simulation

Similar to the traditional Monte Carlo method, we use a vector of key zero-coupon rates to describe a yield curve:

$$\{r_1, \dots, r_i, \dots, r_n\} \quad (1)$$

We assume that these rates are correlated, and the stochastic process of each key rate is described by the lognormal diffusion equation^b

$$\frac{dr_i}{r_i} = \mu_i(t) dt + \sigma_i dz_i \quad (2)$$

where z_i are correlated Brownian motions (*see Numerical Schemes for Stochastic Differential Equation Models*) with a correlation matrix $\mathbf{R}$. Using the current yield curve and the covariance matrix of $\{r_1, \dots, r_i, \dots, r_n\}$, the traditional Monte

Carlo method would directly generate a large number of yield curves. As we pointed out, the portfolio repricing would consume significant computational resources. Moreover, unless the sample size is very large, there are possibilities that the Monte Carlo sample may not cover adequately the tails of the distribution, which are of significance in evaluating a portfolio's risk exposure.

The scenario simulation method takes a different approach. First, one applies principal component (PC) analysis to reduce the dimensionality.^c Most empirical evidence supports the result that the first three PCs can explain almost the entire variation of yield-curve movements. By using the first three PCs, we derive the following approximation for the yield-curve movements:

$$\frac{dr_i(t)}{r_i(t)} \approx \mu_i(t) dt + \delta_{i1} dw_1 + \delta_{i2} dw_2 + \delta_{i3} dw_3 \quad (3)$$

where

$$\delta_{ij} = \sigma_i \beta_{ij} \quad (4)$$

and β_{ij} is the i th component of the j th PC of the correlation matrix $\mathbf{R}$. We note that the principal factors $\{w_i, i = 1, 2, \dots, n\}$ are independent Brownian motions.

In the second step, the problem is further simplified by using the multinomial distribution to discretize the multinormal distribution. In other words, instead of generating a large number of yield curves, each with the same probability, we generate a limited number of scenarios, each with a different probability. For example, we can select seven scenarios for the first PC, five scenarios for the second PC, and three scenarios for the third PC. This yields 105 yield-curve scenarios with different assigned probabilities, thus providing the distribution of yield-curve movements. It has been numerically demonstrated that for risk management purposes, this set of scenario curves is as good as or better than the Monte Carlo method with a large sample size (see [1]). By design, the set of scenarios always includes extreme cases with very small probabilities. Figure 1 summarizes the methodology of the single currency scenario simulation.

Example 1 Japanese Yen (JPY) Scenario Curves. Using RiskMetrics data as of 04/07/1999, we obtain the first three PCs (see **Fault Detection and Diagnosis**) for the correlation matrices of Japanese Yen yield-curve movements as shown in Table 1.

Figure 1 Diagram of single currency scenario simulation model

The columns correspond to zero-coupon rates with respective maturities. The numbers in the first row are all of the same sign, thus the corresponding principal factor is often explained as a “parallel shift” factor. The second factor can be called a *twist* factor and the third one, a *butterfly* factor.

In the scenario simulation model, each principal factor w_i is discretized by a binomial distribution with N_i successive outcomes one standard deviation apart. Since the first principal factor is most important, seven scenarios ($N_1 = 7$) are selected; for the second principal factor five scenarios ($N_2 = 5$) are selected; and three scenarios are selected for the third factor ($N_3 = 3$).^d Altogether, there are ($n_1 = 0, \dots, 6; n_2 = 0, \dots, 4; n_3 = 0, \dots, 2$) possible scenarios, and the total number of scenarios is $7 \times 5 \times 3 = 105$. Because all principal factors are independent of each other, the probabilities of yield-curve scenarios can be calculated easily. As an example,

Table 1 The first three principal components of JPY yield curve

	1 month	3 months	6 months	1 year	2 years	3 years	4 years	5 years	7 years	9 years	10 years	20 years
First PC	0.340	0.440	0.407	0.423	0.892	0.945	0.962	0.965	0.938	0.913	0.883	0.731
Second PC	-0.750	-0.810	-0.716	-0.819	-0.141	-0.043	0.019	0.141	0.297	0.343	0.376	0.461
Third PC	-0.419	0.014	0.420	0.298	-0.170	-0.166	-0.176	-0.094	-0.008	0.039	0.127	0.365

**Figure 2** JPY yield curve scenarios

the probability of scenario ($n_1 = 4, n_2 = 2, n_3 = 1$) is equal to

$$\frac{15}{64} \times \frac{3}{8} \times \frac{1}{2} \approx 4.395\% \quad (5)$$

Figures 2–4 show the Japanese Yen scenario yield curves over a 1-year horizon.^c All curves are zero-coupon yield curves, and the middle curve is the current yield curve 1 year forward. The seven curves

**Figure 3** JPY yield curve scenario**Figure 4** JPY yield curve scenario

in Figure 2 are generated using only the first principal factor. It shows that the changes in the yield levels resemble parallel shifts. Figures 3 and 4 demonstrate that the second factor and the third factor reflect the twist and the butterfly movements of the yield curve, respectively. Each curve is associated with a probability of the corresponding scenario. For example, the third curve from the top of Figure 2 represents scenario (4, 2, 1) whose probability is 4.395%.

Multicurrency Scenario Simulation

The advantage of the scenario simulation method becomes more evident when the portfolio consists of derivative transactions in multiple currencies. In the multicurrency scenario simulation, we use the empirical correlation between principal factors of yield curves of different currencies to Monte Carlo simulate correlated yield-curve scenarios jointly in multiple currencies. This is done by the Gaussian copula method.^f Indeed, we know each discretized principal factor is binomially distributed, so (centering each at zero) we can construct a unique joint distribution of the principal factors of all currencies using these (centered) binomially distributed marginals in addition to using the Gaussian copula with the correlation matrix of the principal factors. This then easily provides a random joint-curve scenario by simply generating a multivariately normally distributed random number.

In greater detail, let

$$\begin{aligned} a_{i+1} &= \Psi^{-1}(F(i)) \quad i = 0, \dots, m; \\ (a_0 &= -\infty, a_{m+1} = +\infty) \end{aligned} \quad (6)$$

where Ψ represents the standard normal cumulative distribution function of the normal distribution, and F represent the binomial cumulative distribution function. Thus, a_i ($i = 0, \dots, m+1$) are the points on the real line such that the area under the normal curve on the segment $[a_i, a_{i+1}]$ equals the binomial probability of state i . For example, if $m = 6$, we have

$$\begin{aligned} a_1 &= -2.15387, a_2 = -1.22986, a_3 = -0.40225, \\ a_4 &= 0.40225, a_5 = 1.22986, a_6 = 2.15387 \end{aligned} \quad (7)$$

The area under the normal curve on $(a_0, a_1]$ is equal to $1/64$, the probability of the first state in this seven-state binomial distribution, and so on.

Define the function $B^{(m)}$ on the real line with values in the set $\{0, \dots, m\}$:

$$B^{(m)}(z) = i \quad \text{if } a_i \leq z < a_{i+1} \quad (8)$$

Clearly, if Z is a normally distributed with mean zero and variance one, then $B^{(m)}(Z)$ is binomially distributed with $m+1$ states.

Now, if X is a k -dimensional normal variate with correlation matrix $\mathbf{Q}$,

$$X = (X_1, \dots, X_k) \sim N(0, \mathbf{Q}) \quad (9)$$

each X_i having mean zero and variance one, define its discretization

$$B^{(m)} = (B^{(m)}(X_1), \dots, B^{(m)}(X_k)) \quad (10)$$

Each coordinate of $B^{(m)}$ is binomially distributed and equals the discretization of the corresponding component of X . As such, this multivariate discretization X preserves the univariate discretization of each component of X . It can be shown that $B^{(m)}$ converges to X with probability one as m increases.

To generate correlated multicurrency yield-curve scenarios requires random samples of $B^{(m)}$. First, we generate a multivariate $N(0, \mathbf{Q})$ normal deviate $x = (x_1, \dots, x_k)$, then simply find between which a_i and a_{i+1} each x_j lies, and thus form $(B^{(m)}(x_1), \dots, B^{(m)}(x_k))$. Recall each $B^{(m)}(x_i)$ represents a currency yield-curve scenario. The above procedure thus generates a joint yield-curve scenario, that is, a yield curve for each currency.

The joint probability density of $B^{(m)}$ can be written as

$$\begin{aligned} \text{prob}[B^{(m)} = (i_1, \dots, i_k)] \\ = \int_{a_{i_1}}^{a_{i_1+1}} \dots \int_{a_{i_k}}^{a_{i_k+1}} \\ \times p(x_1, \dots, x_k) dx_1 \dots dx_k \end{aligned} \quad (11)$$

where $p(x) = p(x_1, \dots, x_k)$ is the multivariate normal density function of X with correlation matrix $\mathbf{Q}$.

Figure 5 illustrates the methodology. First, scenario simulation is performed in each currency. If three factors and a total of 105 scenarios for each currency curve are used, and seven scenarios for each exchange rate are selected, each currency portfolio will have an output with $105 \times 7 = 735$ joint interest rate and exchange rate scenarios, except for the base currency portfolio which has 105 scenarios. Then, to obtain the risk exposure of the whole portfolio in the base currency, joint market scenarios based on the correlation matrix of principal factors and exchange rates are generated using Monte Carlo simulation as described. For a given joint multicurrency market scenario s , the portfolio value $V(s)$ is simply

$$V(s) = \sum_{k=1}^K X_k(s) \cdot V_k(s) \quad (12)$$

Figure 5 Diagram of multicurrency scenario simulation

where X_k is the exchange rate and V_k is the portfolio value of currency k . Using this method, even when a million joint scenarios are generated, only 105 yield curves are produced for each currency, and therefore each transaction has to be priced only 105 times rather than a million times.

In summary, the scenario simulation method makes the simulation computationally practical for very large multicurrency portfolios of fixed-income securities and derivatives.

Applications to Value-at-Risk Estimation and Stress Testing

The scenario simulation model provides an effective alternative to the delta approximation method and the traditional Monte Carlo method. We can directly apply the model by valuing each transaction say, 105 times, and obtain the portfolio's profit and loss distribution, and with it, the portfolio risk exposure statistics. The portfolio's VaR is simply one of the portfolio risk statistics, namely,

$$VaR = \max\{v: \text{Probability}(-\Delta V \leq v) \leq \alpha\} \quad (13)$$

where α is the confidence level and ΔV is the random change in portfolio value. For example, if α is 99%, then with 99% probability the amount of loss $(-\Delta V)$ will be less than VaR.

Usually, portfolio risk parameters, such as delta and gamma, are readily available to risk managers. In this case, the calculation can be further simplified for short horizons. Suppose that δ and γ are the delta

and gamma of the k th currency portfolio. Delta is a vector whose i th component is defined as the first-order derivative of the market value V_k with respect to y_i , the i th bucket forward rate. Gamma is the matrix of the second-order derivatives of V_k with respect to y_i . For a given yield-curve scenario s , its portfolio value change $\Delta V_k(s)$ can be approximated by

$$\Delta V_k(s) \approx \delta \cdot \Delta y(s) + \frac{1}{2} \Delta y(s)^T \cdot \gamma \cdot \Delta y(s) \quad (14)$$

where $\Delta y(s)$ represents the vector of forward rates changes from the current yield curve to the given scenario curve. In contrast to the full simulation method, which requires each transaction be valued in all scenarios, with this method, the delta and gamma of each transaction are calculated only once, using the current yield curves. Once delta and gamma are calculated, the above approximation yields for each scenario s the change $\Delta V_k(s)$ without the need to evaluate the portfolio at the scenario s . Once $\Delta V_k(s)$ is thus calculated, the portfolio's profit and loss distribution and VaRs at various confidence levels can be obtained by the stratified sampling and equation (13) as before.

Example 2 Estimating VaR by Scenario Simulation. Table 2 shows VaR calculation results using scenario simulation method for three simple derivative transactions, all denominated in US Dollars (USD) and with a \$100 million notional. The first transaction is a 5-year receiver swap (*see Securitization/Life; Structured Products and Hybrid Securities*) (party A receives fixed rate and pays 6-month LIBOR); the second transaction party A sells

Table 2 VaR using scenario simulation method

	Swap receiver	Cap	Payer swaption	Portfolio
Full simulation	\$2 722 285	\$2 045 630	\$1 226 831	\$2 975 627
Delta only	2 825 615	1 960 242	1 407 511	3 188 506
Delta and gamma	2 774 731	2 121 828	1 205 577	3 007 058

a 5-year 6% cap, and the third is a 1 year payer swaption into 5-year swap with fixed rate at 7%. Two-week VaRs are calculated using 99% confidence level. The method using both delta and gamma gives closer approximation to the full simulation results than the delta only method. The last column of Table 2 shows VaRs of the portfolio with these three transactions.

The scenario simulation model can also be applied to perform stress testing. VaR analysis is usually supplemented by stress testing, using the data from extraordinary historical market events. It is also important to stress test the assumptions of VaR models such as volatilities and correlations. Because of its computational efficiency, scenario simulation method is particularly suitable for such testing. In particular, the method allows risk managers to examine a portfolio's risk exposures within the tail of a given distribution and to identify specific stress scenarios under which the portfolio may become vulnerable.

Applications to Portfolio's Credit Risk Exposure Estimation

There are three basic ingredients that go into estimating a portfolio's potential credit risk:

1. market value of bonds and transactions for each issuer/counterparty;
2. issuer or counterparty credit quality and default or rating migration probabilities;
3. the recovery rate distribution.

A portfolio will suffer a credit loss if an issuer or a counterparty defaults, the market value of the portfolio with respect to the issuer or the counterparty is positive, and the recovery rate is less than 100%. We have the following basic credit risk model:

$$\text{Credit loss} = \max(0, \text{mark-to-market value}) \times (1 - \text{recovery rate}) \times d \quad (15)$$

where $d = 1$ if counterparty defaults, and 0 otherwise. Clearly estimating credit risk is related to, but more complicated than, market risk estimation. All the above three ingredients are random, and they are usually correlated with each other. Unlike market risk management where the horizon is usually short, say one day or a few days, credit risk management looks at much longer horizons, often the entire life of a transaction.

The scenario simulation model can be applied to estimate a portfolio's credit risk exposure as well as its joint market and credit risk exposure. For a given market scenario (s), we define the credit risk exposure with respect to a counterparty at time t as

$$V_t^+(s) = \max\{V_t(s), 0\} \quad (16)$$

Using the scenario simulation model, $V_t^+(s)$ for all selected scenarios and for various horizons t are readily available, and credit risk parameters such as maximum credit exposure with a given confidence level (credit-VaR) can be calculated. In addition, the correlation of defaults among different issuers/counterparties can be incorporated into the scenario simulation model. For example, in the Gaussian copula (see **Credit Risk Models; Simulation in Risk Management; Default Correlation; Copulas and Other Measures of Dependency**) approach, the joint default distribution $\{d_1, d_2, \dots, d_n\}$ can be mapped into a Gaussian distribution $\Psi(x_1, x_2, \dots, x_n; \Sigma)$, where Σ is the correlation matrix.⁸ The default scenarios can then be generated to compute the potential credit losses under various market scenarios.

Example 3 Market and Credit Exposures of a Multicurrency Portfolio. Figures 6–8 illustrate the simulation results for a multicurrency swap portfolio. The portfolio contains more than 300 interest rate and currency swaps in five different currencies. Figure 6 shows the portfolio's market exposure over a 1-month period. Not surprisingly the simulated distribution

Figure 6 Market exposure distribution

Figure 7 Joint exposure distribution

Figure 8 Default loss distribution

and credit exposure is no longer symmetric as shown in Figure 7. The portfolio's potential loss distribution due to counterparty default is illustrated in Figure 8.

End Notes

Scenario-Based Risk Management and Simulation Optimization

Without uncertainty there is no risk. However, very few – if any – real-world situations are risk free. In the world of deterministic optimization, we often choose to “ignore” uncertainty in a given situation in order to come up with a unique and objective solution to a problem. But in situations where uncertainty is at the core of the problem, as it is in those that involve risk management (*see Role of Risk Communication in a Comprehensive Risk Management Approach*), a different strategy is required.

In the field of optimization, there are various approaches designed to cope with uncertainty. In this context, the exact values that the parameters (e.g., the data) of the optimization problem will have are not known with absolute certainty, but may vary to a larger or lesser extent depending on the nature of the factors they represent. In other words, there may be many possible “realizations” of the parameters, each of which is called a *scenario*.

Sections titled “Scenario Optimization” and “Robust Optimization” briefly describe traditional scenario-based approaches to optimization, such as *scenario optimization* and *robust optimization*. The main section titled “Simulation Optimization” then illustrates an important real world application of a recently emerging approach that is having a profound impact on risk management called *simulation optimization*.

Scenario Optimization

In [1] Dembo offers an approach to solving stochastic programs based on a method for solving deterministic scenario subproblems and combining the optimal scenario solutions into a single feasible decision.

Imagine a situation in which we want to minimize the cost of producing a set J of finished goods. Each good j ($j = 1, \dots, n$) has a per unit production cost c_j associated with it, as well as an associated utilization rate a_{ij} of resources for each finished good. In addition, the plant that produces the goods has a limited amount of each resource i ($i = 1, \dots, m$),

denoted by b_i . We can formulate a deterministic mathematical program for a single scenario s (the scenario subproblem, or SP) as follows:

SP :

$$z^s = \min \sum_{j=1}^n c_j^s x_j \quad (1)$$

$$\text{Subject to: } \sum_{j=1}^n a_{ij}^s x_j = b_i^s \quad \text{for } i = 1, \dots, m \quad (2)$$

$$x_j \geq 0 \quad \text{for } j = 1, \dots, n \quad (3)$$

where c^s , a^s , and b^s respectively represent the realization of the cost coefficient, the resource utilization, and the resource availability data under scenario s . Consider, for example, a company that manufactures a certain type of maple door. Depending on the weather in the region where the wood for the doors is obtained, the cost of raw materials and transportation will vary. The company is also considering whether to expand production capacity at the facility where doors are manufactured, so a total of six scenarios must be considered. The six possible scenarios and associated parameters for maple doors are shown in Table 1.

Therefore, model SP needs to be solved once for each of the six scenarios.

The scenario optimization approach can be summarized in two steps:

1. Compute the optimal solution to each deterministic scenario subproblem SP .
2. Solve a tracking model to find a single, feasible decision for all scenarios.

The key aspect of scenario optimization is the function of the tracking model in step 2. For illustration we introduce a simple form of tracking model. Let p^s denote the estimated probability for the occurrence of scenario s . Then, a simple tracking model for our problem can be formulated as follows:

$$\begin{aligned} \text{Minimize } & \sum_s p^s \left(\sum_j c_j^s x_j - z^s \right)^2 \\ & + \sum_s p^s \left(\sum_{ij} a_{ij}^s x_j - b_i^s \right)^2 \end{aligned} \quad (4)$$

$$\text{Subject to: } x_j \geq 0 \quad \text{for } j = 1, \dots, n \quad (5)$$

Table 1 Possible scenarios for maple doors

Scenario	Capacity	$P(C)(\%)$	Weather	$P(W)(\%)$	$P(\text{scenario})$	Cost c_j	Utilization a_{ij}	Availability b_j
1	Current	50	Dry	33	1/6	Low	High	Low
2			Normal	33	1/6	Medium	Low	Low
3			Wet	33	1/6	High	Low	Low
4	Expanded	50	Dry	33	1/6	Low	High	High
5			Normal	33	1/6	Medium	Low	High
6			Wet	33	1/6	High	Low	High

The purpose of this tracking model is to find a solution that is feasible under all the scenarios, and it penalizes solutions that differ greatly from the optimal solution under each scenario. The two terms in the objective function are squared to ensure nonnegativity. More sophisticated tracking models can be used for various different purposes. In risk management, for instance, we may select a tracking model that is designed to penalize performance below a certain target level.

Robust Optimization

Robust optimization may be used when the parameters of the optimization problem are known only within a finite set of values. The robust optimization framework gets its name because it seeks to identify a robust decision – i.e., a solution that performs well across many possible scenarios.

In order to measure the robustness of a given solution, different criteria may be used. Kouvelis and Yu identify three criteria: (a) absolute robustness, (b) robust deviation, and (c) relative robustness. We illustrate the meaning and relevance of these criteria by describing the robust optimization approach described in [2].

Consider an optimization problem where the objective is to minimize a certain performance measure such as cost. Let S denote the set of possible data scenarios over the planning horizon of interest. Also, let X denote the set of decision variables and P denote the set of input parameters of our decision model. Correspondingly, we let P^s identify the value of the parameters belonging to scenario s , and let F^s identify the set of feasible solutions to scenario s . The optimal solution to a specific scenario s is then

$$z^s = f(X_s^*, P^s) = \min_{X \in F^s} f(X, P^s) \quad (6)$$

We assume here that f is convex. The first criterion, absolute robustness, also known as *worst-case optimization*, seeks to find a solution that is feasible for all possible scenarios and optimal for the worst possible scenario. In other words, in a situation where the goal is to minimize the cost, the optimization procedure will seek the robust solution, z^R , that minimizes the cost of the maximum-cost scenario. We can formulate this as an objective function of the form

$$z^R = \min \left\{ \max_{s \in S} f(X, P^s) \right\} \quad (7)$$

The second criterion, robust deviation, is the one that minimizes the largest deviation from optimality. In other words, we seek to minimize the worst-case deviation that separates the robust solution from the optimal solution to each scenario. The third criterion, relative robustness, is similar to the second, but instead of a direct deviation measure, we use a relative deviation measure with respect to optimality. Suppose for convenience we reformulate the scenario subproblem introduced in the previous section as follows (based on [2, pp. 26–29]):

$$z^s = \min c^s x \quad (8)$$

$$\text{Subject to: } A^s x = b^s \quad (9)$$

$$x \geq 0 \quad (10)$$

Then, the robust deviation problem would be formulated as follows:

$$\text{Minimize } y \quad (11)$$

$$\text{Subject to: } c^s x \leq y + z^s \quad (12)$$

$$A^s x = b^s \quad (13)$$

$$x \geq 0 \quad (14)$$

Variations to this basic framework have been proposed in [3] to capture the risk-averse nature

of decision makers by introducing higher moments of the distribution of z^s in the optimization model and implementing weights as penalty factors for infeasibility of the robust solution with respect to certain scenarios.

Simulation Optimization

Until quite recently, the methods available for finding optimal decisions have been unable to effectively handle the complexities and uncertainties posed by many real-world situations of the form treated by simulation. The areas of scenario optimization and robust optimization described in the previous sections attempt to deal with some of these, but the modeling framework limits the range of situations that can be tackled with such technology.

The complexities and uncertainties that render real-world systems mathematically intractable are the primary reason that simulation is often chosen as a basis for handling decision problems associated with those systems. On one hand, the set of possible scenarios is often unknown *a priori*. On the other hand, the possible combinations of parameters is too numerous to be handled efficiently by methods such as those previously described. Consequently, decision makers must deal with the dilemma that many important types of optimization problems can only be treated by the use of simulation models, but once these problems are submitted to simulation there are no optimization methods that can adequately cope with them.

Recent developments are changing this picture. The field of metaheuristics – the domain of optimization that augments traditional mathematics with artificial intelligence and methods derived from physical, biological, or evolutionary analogs – has witnessed advances yielding effective engines for guiding a series of complex evaluations in the quest for optimal values for the decision variables, as described in [4–9].

Modern simulation optimization tools are designed to solve optimization problems of the following form:

$$\text{Minimize} \quad F(x) \quad (\text{objective function}) \quad (15)$$

$$\text{Subject to:} \quad Ax \leq b \quad (\text{constraints}) \quad (16)$$

$$g_l \leq G(x) \leq g_u \quad (\text{requirements}) \quad (17)$$

$$l \leq x \leq u \quad (\text{bounds}) \quad (18)$$

where the vector x of decision variables includes variables that range over continuous values and variables that only take on discrete values (both integer values and values with arbitrary step sizes).

The objective function $F(x)$ is typically highly complex; under the context of simulation optimization $F(x)$ represents a performance measure output by the simulation, and may be any mapping from a set of values x to a real value. The constraints represented by inequality $Ax \leq b$ are linear (given that nonlinearity in the model is embedded within the simulation itself), and the coefficient matrix A and the right-hand-side values corresponding to vector b must be known. The requirements $g_l \leq G(x) \leq g_u$ impose simple upper and/or lower bounds on a function that can be linear or nonlinear and is an output of the simulation. The values of the bounds g_l and g_u must be known constants. All the variables are bounded and some may be restricted to be discrete, as previously noted. Each evaluation of $F(x)$ and $G(x)$ requires a simulation of the system. By combining simulation and optimization, a powerful design tool results.

Optimizers designed for simulation embody the principle of separating the method from the model. In such a context, the optimization problem is defined outside the complex system. Therefore, the evaluator (i.e., the simulation model) can change and evolve to incorporate additional elements of the complex system, while the optimization routines remain the same. Hence, there is a complete separation between the model that represents the system and the procedure that is used to solve optimization problems defined within this model.

The optimization procedure uses the outputs from the system evaluator, which measures the merit of the inputs that were fed into the model. On the basis of both current and past evaluations, the method decides upon a new set of input values (see Figure 1).

Provided that a feasible solution exists, the optimization procedure ideally carries out a special search

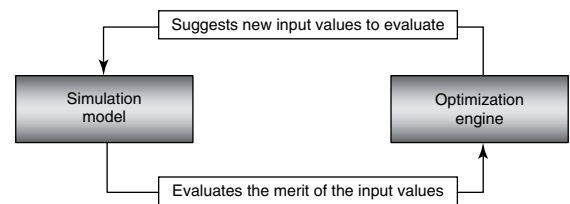

Figure 1 Coordination between optimizer and simulator

where the successively generated inputs produce varying evaluations, not all of them improving, but which over time provide a highly efficient trajectory to the globally best solutions. The process continues until an appropriate termination criterion is satisfied (usually based on the user's preference for the amount of time devoted to the search).

The simulation optimization framework is very flexible in terms of the performance measures the decision maker wishes to evaluate. In fact, the only limitation is not on the side of the optimization engine, but on the simulation model's ability to evaluate performance based on specified values for the decision variables. In order to provide in-depth insights into the use of simulation optimization in the context of risk management, we present a practical application through the use of an illustrative example in the context of optimal portfolio selection.

Example: Selecting Optimal Portfolios of Projects

The energy industry uses project portfolio optimization to manage investments in exploration and production, as well as power plant acquisitions [10, 11]. Decision makers typically wish to maximize the return on invested capital, while controlling the exposure of their portfolio of projects to various risk factors.

The following example involves a company that has 61 potential projects in its investment funnel. Each type of project requires an initial investment and a certain number of business development, engineering, and earth sciences personnel. The company has a budget limit for its investment opportunities, and a limited number of personnel in each skill category. Projects may start in different time periods, but there is a restricted window of opportunity of up to 3 years for each project. The company must select a set of projects to invest in that will best further its corporate goals.

Probably the best-known model for portfolio optimization is rooted in the work of Nobel laureate Harry Markowitz. The model, called the *mean-variance model* [12], is based on the assumption that the expected portfolio returns will be normally distributed. The model seeks to balance risk and return in a single objective function, as follows.

Given a vector of portfolio returns r , and a covariance matrix Q of returns, then we can formulate

the model as follows:

$$\text{Maximize} \quad r^T w - k w^T Q w \quad (19)$$

$$\text{Subject to:} \quad \sum_i c_i w_i = b \quad (20)$$

$$w \in \{0, 1\} \quad (21)$$

where k represents a coefficient of the firm's risk aversion, c_i represents the initial investment in project i , w_i is a binary variable representing the decision whether to invest in project i , and b is the available budget. We will use the mean-variance model as a base case for the purpose of comparing with other selected models of portfolio performance.

To facilitate our analysis, we make use of the OptFolio® software that combines simulation and optimization into a single system specifically designed for portfolio optimization [13–15].

We examine three cases to demonstrate the flexibility of this method to enable a variety of decision alternatives that significantly improve upon traditional mean-variance portfolio optimization, and illustrate the flexibility afforded by simulation optimization approaches in terms of controlling risk. The results also show the benefits of managing and efficiently allocating scarce resources like capital, personnel, and time. The weighted average cost of capital, or annual discount rate, used for all cases was 12%.

Case 1: Mean-Variance Approach

In this first case, we implement the mean-variance portfolio selection method of Markowitz described above. The decision is to determine participation levels (0 or 1) in each project with the objective of maximizing the expected net present value (NPV) of the portfolio while keeping the standard deviation of the NPV below a specified threshold of \$140 M. We denote the expected value of the NPV by μ_{NPV} , and the standard deviation of the NPV by σ_{NPV} . This case can be formulated as follows:

$$\text{Maximize} \quad \mu_{NPV} \quad (\text{objective function}) \quad (22)$$

$$\text{Subject to:} \quad \sigma_{NPV} < \$140 \text{ M} \quad (\text{requirement}) \quad (23)$$

$$\sum_i c_i x_i \leq b \quad (\text{budget constraint}) \quad (24)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j$$

(personnel constraints) (25)

All projects must start in year 1

$$x_i \in \{0, 1\} \quad \forall i \text{ (binary decisions)} \quad (26)$$

The optimal portfolio has the following performance metrics:

$$\begin{aligned} \mu_{NPV} &= \$394 \text{ M}, \\ \sigma_{NPV} &= \$107 \text{ M}, \\ P(5)_{NPV} &= \$176 \text{ M} \end{aligned} \quad (27)$$

where $P(5)_{NPV}$ denotes the 5th percentile of the resulting NPV probability distribution (i.e., the probability of the NPV being lower than the $P(5)$ value is 5%).

The bound imposed on the standard deviation in equation (23) does not seem binding. However, owing to the binary nature of the decision variables, no project additions are possible without violating the bound. Figure 2 shows a graph of the probability distribution of the NPV obtained for 1000 replications of this base model. The thin line represents the expected value.

Case 2: Risk Controlled by 5th Percentile

In the context of risk management, statistics such as variance or standard deviation of returns are not always easy to interpret and other measures may be more intuitive and useful. For example, it is clearer to say, “there is a 95% chance that the portfolio return is above some value X” than to say that the standard deviation is \$107M. This measure can be easily implemented in a simulation optimization procedure

Figure 2 Mean-variance portfolio

by imposing a requirement on the 5th percentile of the resulting distribution of returns. In case 2, the decision is to determine participation levels (0, 1) in each project with the objective of maximizing the expected NPV of the portfolio, while keeping the 5th percentile of the NPV distribution above the value determined in case 1. This is achieved by imposing the requirement in equation (30) on the model below. In other words, we want to find the portfolio that produces the maximum average return, as long as no more than 5% of the observations fall below \$176M. Also, in this case we allow for delays in the start dates of projects, according to windows of opportunity defined for each project. In order to achieve this, we have created copies of a project that are shifted by one, two or three periods into the future (according to the windows of opportunity defined for each project). Mutual exclusivity clauses ensure that only one start date for each project is selected. For example, to represent the fact that Project A can start at time $t = 0, 1$ or 2, we include the following mutual exclusivity clause as a constraint:

$$\text{Project } A_0 + \text{Project } A_1 + \text{Project } A_2 \leq 1 \quad (28)$$

The subscript following the project name corresponds to the allowed start dates for the project, and the constraint only allows at most one of these to be chosen.

$$\text{Maximize} \quad \mu_{NPV} \quad (29)$$

$$\text{Subject to:} \quad P(5)_{NPV} > \$176 \text{ M} \quad (\text{requirement}) \quad (30)$$

$$\sum_i c_i x_i \leq b \quad (\text{budget constraint}) \quad (31)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j$$

(personnel constraints) (32)

$$\sum_{m_i \in M} x_i \leq 1 \quad \forall i$$

(mutual exclusivity) (33)

$$x_i \in \{0, 1\} \quad \forall i \quad (\text{binary decisions}) \quad (34)$$

where m_i denotes the set of mutually exclusive projects related to project i . In this case we have replaced the standard deviation with the 5th percentile

as a measure of risk containment. The resulting portfolio has the following attributes:

$$\begin{aligned}\mu_{NPV} &= \$438 \text{ M}, \\ \sigma_{NPV} &= \$140 \text{ M}, \\ P(5)_{NPV} &= \$241 \text{ M}\end{aligned}\quad (35)$$

By using the 5th percentile instead of the standard deviation as a measure of risk, we are able to obtain an outcome that shifts the distribution of returns to the right, compared to case 1, as shown in Figure 3.

This case clearly outperforms case 1. Not only do we obtain significantly better financial performance, but we also achieve a higher personnel utilization rate, and a more diverse portfolio.

Case 3: Probability Maximizing and Value at Risk

In case 3, the decision is to determine participation levels (0, 1) in each project with the objective of maximizing the probability of meeting or exceeding the mean NPV found in case 1. This objective is expressed in equation (36) of the following model.

$$\text{Maximize} \quad P(NPV \geq \$394 \text{ M}) \quad (36)$$

$$\text{Subject to:} \quad \sum_i c_i x_i \leq b \text{ (budget constraint)} \quad (37)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j$$

(personnel constraints) (38)

$$\sum_{m_i \in M} x_i \leq 1 \quad \forall i$$

(mutual exclusivity) (39)

$$x_i \in \{0, 1\} \quad \forall i \text{ (binary decisions)} \quad (40)$$

Figure 3 Portfolio risk controlled by $P(5)$

This case focuses on maximizing the chance of achieving a goal and essentially combines performance and risk containment into one metric. The probability in equation (36) is not known *a priori*, so we must rely on the simulation to obtain it. The resulting optimal solution yields a portfolio that has the following attributes:

$$\begin{aligned}\mu_{NPV} &= \$440 \text{ M}, \\ \sigma_{NPV} &= \$167 \text{ M}, \\ P(5) &= \$198 \text{ M}\end{aligned}\quad (41)$$

Although this portfolio has a performance similar to the one in case 2, it has a 70% chance of achieving or exceeding the NPV goal. As can be seen in the graph of Figure 4, we have succeeded in shifting the probability distribution even further to the right, therefore increasing our chances of exceeding the returns obtained with the traditional Markowitz approach. In addition, in cases 2 and 3, we need not make any assumption about the distribution of expected returns.

As a related corollary to this last case, we can conduct an interesting analysis that addresses value at risk (VaR). In traditional (securities) portfolio management, VaR is defined as the worst expected loss under normal market conditions over a specific time interval and at a given confidence level. In other words, VaR measures how much the holder of the portfolio can lose with probability equal to α over a certain time horizon [16]. In the case of project portfolios, we can define VaR as the probability that the NPV of the portfolio will fall below a specified value. Going back to our present case, the manager may want to limit the probability of incurring negative returns. In this example, we formulate the problem in a slightly different way: we

Figure 4 Probability-maximizing portfolio

still want to maximize the expected return, but we limit the probability that we incur a loss to $\alpha = 1\%$ by using the requirement shown in equation (43) as follows:

$$\text{Maximize} \quad \mu_{NPV} \quad (42)$$

$$\text{Subject to:} \quad P(NPV < 0) \leq 1\% \text{ (requirement)} \quad (43)$$

$$\sum_i c_i x_i \leq b \quad \text{(budget constraint)} \quad (44)$$

$$\sum_i p_{ij} x_i \leq P_j \quad \forall j \quad \text{(personnel constraints)} \quad (45)$$

$$\sum_{m_i \in M} x_i \leq 1 \quad \forall i \quad \text{(mutual exclusivity)} \quad (46)$$

$$x_i \in \{0, 1\} \quad \forall i \quad \text{(binary decisions)} \quad (47)$$

The portfolio performance under this scenario is

$$\mu_{NPV} = \$411 \text{ M}, \sigma_{NPV} = \$159 \text{ M}, P(5) = \$195 \text{ M} \quad (48)$$

These results from the VaR model turn out to be slightly inferior to the case where the probability was maximized. This is not a surprise, since the focus is on limiting the probability of downside risk, whereas before, the goal was to maximize the probability of obtaining a high expected return. However, this last analysis could prove valuable for a manager that wants to limit the VaR of the selected portfolio. As shown here, for this particular set of projects, a very good portfolio can be selected with that objective in mind.

Conclusions

Practically every real-world situation involves uncertainty and risk, creating a need for optimization methods that can handle uncertainty in model data and input parameters. We have briefly described two popular methods, *scenario optimization* and *robust optimization*, that seek to overcome limitations of classical optimization approaches for dealing with uncertainty, and which undertake to find high-quality

solutions that are feasible under as many scenarios as possible. However, these methods are unable to handle problems involving moderately large numbers of decision variables and constraints, or involving significant degrees of uncertainty and complexity. In these cases, simulation optimization is becoming the method of choice. The combination of simulation and optimization affords all the flexibility of the simulation engine in terms of defining a variety of performance measures as desired by the decision maker. In addition, as we demonstrate through a project portfolio selection example, modern optimization engines can enforce requirements on one or more outputs from the simulation, a feature that scenario-based methods cannot handle. Finally, simulation optimization produces results that can be conveyed and grasped in an intuitive manner, providing an especially useful tool for identifying improved business decisions under risk and uncertainty.

Comparative Risk Assessment

MARCO BETTER AND FRED GLOVER

Scientific Uncertainty in Social Debates Around Risk

There are three primary audiences in science policy: scientists, policymakers, and the public [1]. Current issues in environment and health are often clouded with uncertainty. The public is becoming increasingly alarmed over potential adverse health effects stemming from chemical toxicants and industrial wastes being discharged into the environment at all levels (i.e., local, national, and global). They look to scientists to evaluate, assess, and identify potential risks. There is also an expectation that policy makers make informed decisions, on the basis of scientific evidence, to implement the appropriate solutions that will “solve” the environmental problems of the day. However, mismanagement of past risk issues, by both scientists and policy makers, have left the public distrustful (*see Stakeholder Participation in Risk Management Decision Making*).

When risk controversies arise, a power struggle may result between the competing interests, ideologies, values, and approaches employed by the actors involved: industry, scientists, policy makers, the media, and the public. Each group’s conception of what constitutes “safe” may differ. The typical response from scientists and industry during risk controversies is that the public is “irrational”, the media “twists” the scientific information, and policy makers rarely listen to “objective” scientific evidence. Although such sentiments may be superficially plausible, they reflect a misunderstanding of the uncertain nature of living in a technological society and the limitations of risk analysis [2].

Prior to the 1960s, analytical chemistry was based largely on the senses of sight and smell. Since then, considerable technological and disciplinary advances within analytical chemistry have enabled scientists to identify the presence of elements and chemical compounds as low as n parts per billion; *detection limits* (*see Detection Limits*) for some substances have reached as low as parts per quadrillion [3]. Such advances in measurement sensitivity have often led to a redefinition of toxicity in terms of trace elements and compounds. However, this dependence

on apparently precise numbers, which conveys an impression that science is accurate in its estimates, has done comparatively little to objectify the processes for determining when such compounds are toxic in terms of their risk to ecosystems or human health. Such decisions are, in part, the consequence of social and political processes taking place among scientists and policy makers [4]. Thus, what begins as a scientific measurement and analysis problem frequently turns into an arena of interpretation and social debate [3]. These debates typify how uncertainties in science are managed in a policy context.

Science as a Knowledge Producer

The process of scientific discovery is essential in the construction of scientific knowledge claims. These take place in established institutions: laboratories; working groups; disciplines; peer-review committees; journal publications; and scientific prizes, such as the Nobel prize [5]. Although these institutions provide avenues for the development of scientific facts, it is critical that their “consumption” in a social world be analyzed. In other words, it is important to examine what happens once scientific claims leave the laboratories and enter journals, professional meetings, reports [6], regulatory agencies [7], and the media [8]. It is through the consumption of scientific claims that experts seek to establish boundaries as to who can legitimately speak as an authority. “Authority” can only exist when the production of knowledge claims are conferred to some but denied to others [6]. Latour [9] uses the analogy of the two-faced Janus to depict stages of science: ready-made science (where facts are agreed upon) and science in action (where facts and evidence are not immutable and are subject to debate). It is during this latter stage that “credibility contests” occur [6] where the credibility of both the producer of the knowledge claims and of the challenger are equally “on the line” [8].

Although credibility contests may occur privately, (i.e., in an environment where there is a controlled membership, like a scientific meeting or a peer-reviewed journal), it is when these contests move into the public domain that scientists may present a unified position to protect the autonomy of science [6]. A public disagreement can occur once scientific facts are brought out into the open through the courts or in

the media. For example, in the area of climate change, scientists were instrumental in putting the issue on the policy agenda. Although some scientists raised disconfirming evidence, these alternative views were shut out [10].

Scientists seek to convince others of the importance of their work to secure funding, and consequently control the direction of the research agenda [5]. Issues of uncertainty are pivotal to this process. In a science-policy domain, there needs to be a balance in the level of uncertainty: too much and the problem seems daunting; too little and there is no motivational push for research funds dedicated to study the issue [11]. Consequently, “uncertainty” becomes both a social and cultural process used as a forum for competing ideologies and interests [12].

From a risk perspective, risks need to be first identified and measured by science before they can gain social recognition [2]. Hence, risks are “invisible” (i.e., not objective forms of knowledge) until they are measured. These knowledge claims then have to be translated within a policy domain, where only that knowledge that is made “meaningful” gains political attention. Salter [7] refers to these processes as “mandated science”; in other words, scientific evidence is used in policy making.

The Uptake of Science to Policy

There is insufficient understanding of how environmental health policy decisions are made in the face of scientific uncertainty (*see Environmental Health Risk*). It is felt that only through the development of more precise methodologies, the continuous replication of results, and increasingly rigorous studies science will be able to resolve much of the uncertainty, possibly making the task of the policy makers easier. Similarly, there is some debate as to whether better science will lead to greater certainty in decision making. The tendency in science is to reduce phenomena to examinable components in the search for specific cause and effect relationships. This is not an easy task in environmental health where there is a multitude of exposures, confounders, and effects. It becomes much more difficult to determine if certain health effects are the result of a dominant cause or if they are due to a combination of environmental assaults [13]. As such, social considerations of what constitute important exposures and acceptable

risk need to be incorporated into regulatory decisions. One way to understand the interrelationships between various actors in the policy subsystem is through an examination of “epistemic communities” [14].

Conceptually, “epistemic communities” evolved as a means to explain the translation of knowledge and evidence into policy action within a complex international environmental arena. Defined as a network of scientific experts with an authoritative claim to policy-relevant knowledge [14], an epistemic community provides consensual knowledge regarding issues of uncertainty, thereby facilitating policy intervention. Jasanoff and Wynne [15, p. 51] outline four defining characteristics of an epistemic community:

- shared normative and principled beliefs providing a value-based rationale for the community’s proposed social actions;
- shared causal beliefs, including professional judgments linking causal explanations to possible policy actions;
- shared notions of validity including intersubjective, internally defined criteria for establishing valid knowledge; and
- a shared policy endeavor based on a commonly recognized set of problems to be solved.

Common features of these characteristics involve shared values and ideas for preferred policy solutions to identified problems. In other words, “knowledge” and “facts” are viewed and accepted in specifically defined ways according to preset criteria for inclusion and exclusion (e.g., the scientific method). Epistemic communities are often able to define problems in a particular light making some solutions more attractive to decision makers [16]. In an epistemic community “membership” and “behavior” are peer controlled and monitored [9].

Critiques of the concept of “epistemic communities” argue that the role of “power” in the policy arena is typically ignored [17]. There is an assumption that it will only be “expert knowledge” that will sway policy decisions. Yet, policy decisions are usually made on the basis of a number of reasons with expert knowledge being the only one input. Moreover, scientific facts are often not disputed; it is the interpretation of those facts that lead to dissenting opinions and uncertainty. Jamieson argues that science is culturally viewed as a knowledge producer, and consequently, often it cannot bring public decisions to closure. Too

frequently, issues of uncertainty are paramount, often pitting experts against experts – hence the need to control the level of “uncertainty” in both science and policy. The other main critique is that, in categorizing a group of scientists as an epistemic community, shared beliefs that may transfer between communities in a policy subsystem may be masked. The assumption is that communities are homogenous, when in reality, there can be a number of differences within a community group and similarities with members in different epistemic communities [17]. However, by adopting more interpretive approaches, some of these differences can be revealed.

Policy analysis to date has largely been dominated by a rational and incrementalist approach. A rational approach to policy analysis assumes that the intended policy goals are clear and agreed upon, the means of evaluation are well defined, and information about the consequences is complete. Rational policy approaches have been criticized as reflecting an extremely naive view of reality. They make the assumption that decisions are made in a value-free, linear, and sequential manner by completely informed individuals [18]. An alternative to such approaches is incrementalism, where policy decisions are made in small cumulative steps. Incrementalism does not assume a value-free approach. Rather, it recognizes that values play a role in how options and alternatives are assessed. Moreover, there is an understanding that “perfect” information does not exist [19]. However, it is the interpretive approaches that have been gaining increasing attention in the policy literature [20]. Interpretive approaches focus on language and meaning as ways to examine the underlying social context of an issue. Interpretive approaches respond to researchers’ needs for understanding how a policy is “framed” or what it “means” [20]. They also involve an analysis of the role that members of a policy subsystem may play in problem definition, as well as how science and policy become coproducers of relevant knowledge [15].

A useful conceptual framework for understanding the construction and contest of scientific knowledge claims is “agenda-setting” – that is, how issues move on or off an agenda at any given time. Largely informed by the policy literature, agenda-setting analyses can assist in the examination of scientific discourses surrounding a public policy issue characterized by uncertainty. Kingdon [16] outlines three factors that influence the agenda-setting process; these have been modified for a scientific discourse

(see [11]). The first is problem recognition. In any given moment, there is competition of ideas within a policy arena. Those ideas that gain recognition move higher up the agenda to provide a focal point for different science and policy actors. Sometimes, problems are recognized by “focusing events”, which will draw attention to the issue through a key scientific study and its uptake by a regulatory body. Second, in a regulatory arena, scientific analyses are requested to address identified policy problems. However, not all analyses are given the same level of attention, nor do they adequately address the policy problem as it is in the process of being defined by others. If the scientific analysis addresses the identified problem, it will determine for how long that science remains relevant. New scientific knowledge may provide a better understanding of the problem, thereby “tip-ping” the issue into the public/political consciousness. This process is by no means simple. The science must resonate with the values and assumptions of the decision makers for it to remain relevant. The political process itself is the third factor that may influence the science agenda. The “national mood”, public opinion polls, election results, or changes in the administration will influence the nature and level of attention that an issue may receive on the agenda [16] as well as the funding that may be attached to some research agendas [21].

When Science and Policy Meet the Public

Throughout processes of scientific uncertainty and the uptake (or not) of scientific evidence in a policy domain, the role played by the public is often obscured. By and large, the public is viewed as innumerate and scientifically illiterate. However, the public has a greater understanding of the role of science in understanding risk than scientists have of how public attitudes and beliefs are formed within a political participatory system. Considerable research has been dedicated to the public understanding of science (*cf.* [15, 21, 22]), including an academic journal of the same name. This body of literature has shown that tensions lie when the public, operating in a “demosphere” [23], do not fully trust or accept potentially dangerous or uncertain scientific evidence arising from studies in the “technosphere” [15]. It is not that the public are irrational, rather that they incorporate multiple considerations – social,

cultural, political – beyond scientific evidence when making decisions about what is “risky” (see [24]). This has led some to call for the coproduction of shared knowledge between scientists and lay audiences [25]. These processes are not without their challenges and much more research is needed to identify optimum strategies to effect positive and meaningful public participation in the face of science-policy uncertainty.

Summary

When existing scientific understandings are contested or different scientific evidence are used within a policy arena, they enter the domain of mandated science [7], where objective rationality cannot be maintained. Policy makers can choose to use scientific uncertainty as a means to justify a decision that runs counter to the evidence, or equally, uncertainty can be used to justify that no policy decision is needed. For the public, lay understandings of a risk situation, based on personal experiences, oral histories, or the media, may factor into their decision making process. Hence, although there is often a recognition among the public that scientific evidence is a necessary condition, it is not sufficient. As Leiss [26] contends, presently there is a divide between quantitative risk assessments – which reflect a presentation of risk information – and public understanding of those risks, a divide that needs to be addressed through the development of good risk communication practice. Part of this process involves knowledge translation of scientific evidence in plain language; sensitivity to the different sets of “knowledge” (social, cultural, and local) that the public uses to understand risk situations; and concerted efforts to work together as partners to develop shared understanding – both expert and lay.

Role of Risk Communication in a Comprehensive Risk Management Approach

Considerations in Planning for Successful Risk Communication

Securitization/Life

Securitization can be defined as the isolation of a pool of assets (or liabilities or the rights to a set of cash flows) and the repackaging of those assets (or liabilities or cash flow rights) into securities that are traded in capital markets (*see Asset–Liability Management for Life Insurers*). Insurance companies have traditionally been seen as risk warehouses – they would take on insurance risks and bear them themselves – and securitization allows them to move toward a model in which they become risk intermediaries instead – that is, they originate risks, but repackage them and sell them on. The risk-intermediary model of an insurance company has many attractions over the warehouse model, because it is often more efficient for many types of traditional insurance risks to be traded in capital markets rather than held on-balance sheet in risk warehouses, with consequential capital or reserving requirements.

Securitization began in the 1970s when banks in the United States began to sell off pools of mortgage-backed loans. In the 1980s, they then started to sell off other assets, such as automobile, credit card and home equity loans. The amounts involved in these asset-backed security (ABS) arrangements grew rapidly, and by 2002 some \$450 billion dollars worth of assets had been securitized [1]. By comparison, insurance companies have been very slow to catch on to securitization. The first insurance company securitizations related to property and casualty, most notably the catastrophe (“cat”) bonds developed in the 1990s: these securitized extreme property losses arising from natural disasters such as earthquakes and hurricanes. The first life securitizations took place in the late nineties, and took the form of sales of rights to future profits from blocks of life policies and annuities. The pace of innovation in life securitization then started to pick up, and recent developments include the launch of reserve funding (or capital arbitrage) securitizations, mortality and longevity bonds, and, most recently, pension bulk buyout securitizations. However, the amounts involved in life securitizations are still very small compared to those involved in bank securitizations.

The Mechanics of Securitization

The basic idea behind securitization is to move an asset off-balance sheet. (We focus on asset

securitizations for convenience, but similar principles apply to liability securitizations.) This is usually done by transferring the asset (or liability) to a special purpose vehicle (SPV). This SPV is a passive entity that is specially created to house the asset and issue securities using the asset as collateral. The SPV then issues securities to investors who contribute funds to the SPV. The SPV also remits some or all of these funds to the originating institution, which in return transfers the asset or the rights to the cash flows generated by the asset to the SPV. Many of these ABS arrangements involve tranching – the SPV issues different classes of security with different claims and different seniority rights to the underlying cash flows. The tranches themselves can be designed to appeal to different classes of investors and mitigate asymmetric information problems, and thus increase the overall value of the securitization [2]. In many cases, the SPV also enters into a swap: for example, if the underlying cash flows from the asset are not interest sensitive, but if it is perceived that the investors want interest-sensitive coupon payments, then an SPV might swap the fixed payments from the underlying asset into floating payments and issue securities with floating coupon payments. The swap counterparty then becomes another participant in the securitization arrangement.

Most of these arrangements also involve credit enhancement features to protect one or more participating parties against default risk. These features include over-collateralization (where the value of the assets transferred to the SPV exceeds the value of the securities it issues), subordination (where the SPV issues securities with varying levels of seniority), and external guarantees such as parental guarantees, letters of credit, credit insurance, and reinsurance. Many SPVs also include an arrangement by which the originating life institution continues to service the original customers. This is especially important in life securitizations where there is a need to ensure that policyholders do not allow their policies to lapse.

Benefits of Securitization

Life securitizations offer many potential benefits to both the companies that engage in them and to outside investors. In general terms, securitization enables companies to unbundle the different functions associated with traditional insurance – and in particular, to separate out the policy origination function from

the investment management, policy servicing, and risk-bearing functions associated with insurance. This enables insurance companies to exploit the benefits of specialization and make more efficient use of capital. Securitization also gives insurance companies access to the capital available in the capital markets, which vastly exceeds the capital available through traditional channels such as *reinsurance* (see **Reinsurance**). Securitization also offers insurance companies new hedging tools and the potential for better risk management. In addition, it helps make insurance-related positions more marketable and therefore more liquid, and improves the transparency of on-balance sheet positions that have traditionally been very opaque.

Securitization also offers insurance companies more specific benefits. It allows companies to unlock embedded value, monetize the present value of future cash flows from a block of business, and release capital for other uses. Insurance companies can use securitization to lay off unwanted risks – for example, they might use securitization to exit a particular line of business or hedge against extreme mortality risks – which are then passed on to the capital markets. It can also help firms exploit arbitrage opportunities and, in particular, it can relieve the capital strain imposed by conservative capital requirements on certain lines of business. Other firms with large pension funds can also use life securitizations to lay off the *longevity risks* (see **Longevity Risk and Life Annuities**) in their pension funds, as evidenced by the emerging pension fund buyout market in the United Kingdom; such securitizations are potentially very useful because they can relieve firms of their pension fund risks and leave them free to concentrate on their core businesses.

For their part, investors can benefit from securitization in various ways. The most obvious benefit is that it offers them the opportunity to invest in life-related risks. These provide not only new investment outlets involving mortality and longevity risks that were previously inaccessible to them but also particularly attractive outlets because life risks have little or no correlation with most other risks; life securitizations therefore have low or zero betas relative to traditional financial market risks, and this means that they add little extra risk to a diversified portfolio. Investors can therefore improve the risk-expected return efficiency of their portfolios by investing in life securitizations. Suitably designed life securitizations

can also provide investors with investment opportunities that are tailor-made for their risk appetites and expertise. For example, investors who want exposure to life risks but are not particularly knowledgeable about them might wish to invest in tranches with high seniority, whereas more informed investors might wish to invest in riskier tranches where their superior knowledge gives them the opportunity to earn higher returns.

“Block of Business” Securitizations

The earliest securitizations are “block of business” securitizations. (For a more extensive treatment of these securitizations, see [1].) These have been used to capitalize expected future profits from a block of business, recover embedded values, and exit from a geographical line of business. The last of these motivations is obvious, and the first two arise from the fact that the cost of writing new life policies is usually incurred in the first year of the policy and then amortized over the remainder of its term. This means that writing new business puts pressure on a company’s capital. Securitization helps to relieve this pressure by allowing the company immediate access to its expected future profits, and securitization is an especially attractive option when the company is experiencing rapid growth in a particular line of business. Some examples of these securitizations are a set of 13 transactions carried out by American Skandia Life Assurance Company (ASLAC) over 1996–2000; these were designed to capitalize the embedded values in blocks of variable annuity contracts issued by ASLAC in order to fund continued expansion in the variable annuity business.

Block of business securitizations have also been issued in conjunction with demutualizations. When an insurance company demutualizes, it creates a situation in which the new shareholders have a conflict of interest with the prior participating policyholders (see, e.g. [3]). A natural solution to this conflict of interest is to put prior participating policies into closed blocks and then securitize them.

Regulatory Reserving (XXX) Securitizations

Another form of life securitization is a regulatory reserving securitization, sometimes also known

as *reserving funding* or *XXX securitizations*. These arrangements are designed to give life insurers relief from excessively conservative regulatory reserving or capital requirements, and are used to release capital that can be used to finance new business or reduce the cost of capital. An early example of this type of securitization was a \$300 million deal arranged by First Colony Life Insurance Company through an SPV known as *River Lake Insurance Company* to obtain capital relief under regulation XXX. This regulation imposes excessively conservative assumptions in the calculation of the regulatory reserve requirement on some types of life policies with long-term premium guarantees.

Some traditional solutions to this type of problem are letters of credit or reinsurance, but these can be expensive and sometimes difficult to obtain. Where securitization is used, the investments made into the SPV provide collateral for the term policies written by the insurance company, and thus reduce its XXX regulatory reserves. In return, the insurer would pay premiums into the SPV, and the SPV would enter into a fixed-for-floating swap to exchange the fixed premiums paid by the insurer into the floating payments typically owed to the note-holding investors. Typically, payments would be credit enhanced and the notes would amortize over time as obligations on the underlying policies are gradually paid off. If no adverse events occur, the investors would receive the premiums paid out by the insurer; and if adverse events did occur, then the SPV would release funds to cover the shortfall.

Mortality and Longevity Bonds

Other recent securitizations are mortality and longevity bonds. The former are bonds with at least one payment tied to a mortality index, and their purpose is to protect life insurers and annuity providers against the adverse consequences of an unanticipated extreme deterioration in mortality. The latter are bonds with one or more payments tied to a longevity-related variable such as the survivorship rate of a specified cohort, and are designed to protect insurance companies or annuity providers against an unanticipated increase in longevity. More details on these instruments are provided by Blake *et al.* [4].

The first mortality bond was the Swiss Re 3-year mortality catastrophe bond, which was issued in

December 2003 and matured on 1 January 2007. The bond was designed to reduce Swiss Re's exposure to a catastrophic mortality deterioration (e.g., such as that associated with a repeat of the 1918 Spanish Flu pandemic). The issue size was \$400 million, and investors received quarterly coupons set at 3-month US dollar London Interbank Offered Rate (LIBOR) + 135 basis points. However, the principal repayment was contingent on a specified index of mortality rates across the United States, United Kingdom, France, Italy, and Switzerland. The bond was issued *via* an SPV called *Vita Capital* (VC), which invested the \$400 million principal in high-quality bonds and swapped the income stream on these for a LIBOR-linked cash flow.

The bond helped Swiss Re to unload some of its extreme mortality risk, but it is also likely that Swiss Re was mindful of its credit rating and wanted to reassure rating agencies about its mortality risk management. Furthermore, by issuing the bond themselves, Swiss Re were not dependent on the creditworthiness of other counterparties should an extreme mortality event occur. The bond therefore gave Swiss Re some protection against extreme mortality risk without requiring that the company acquire any credit risk exposure in the process. The Swiss Re bond issue offered a considerably higher return than similarly rated floating-rate securities and was fully subscribed. Investors in the bond also included a number of pension funds. These would have been attracted partly by the higher coupons, and also by the hedging opportunities that it offered, given that a mortality event that would have triggered a reduction in the repayment of the bond would presumably have reduced their own pension liabilities as well.

In April 2005, Swiss Re announced the issue of a second life catastrophe bond with a principal of \$362 million, using a new SPV called *Vita Capital II*. The maturity date is 2010 and the bond was issued in three tranches: Class B (\$62 million), Class C (\$200 million), and Class D (\$100 million). The principal is at risk if, for any two consecutive years before maturity, the combined mortality index exceeds specified percentages of the expected mortality level (120% for Class B, 115% for Class C, and 110% for Class D). This bond was also fully subscribed.

The first longevity bond was announced in November 2004. This was to have been issued by the European Investment Bank (EIB), with BNP Paribas

as the designer and originator and Partner Re as the longevity risk reinsurer. The face value of the issue was to be £540 million and the maturity was 25 years. The bond was to have been an annuity (or amortizing) bond with floating coupon payments, and its innovative feature was to link the coupon payments to a cohort survivor index based on the realized mortality rates of English and Welsh males aged 65 in 2002. The EIB/BNP Paribas/Partner Re Longevity Bond was designed to help pension plans hedge their exposure to longevity risk. However, the bond did not attract sufficient investor interest to be launched, and was subsequently withdrawn. One possible reason for its slow take-up was the likelihood that using the bond as a hedge might have involved a considerable amount of basis risk. Another possibility was that the amount of capital required was high relative to the reduction in risk exposure, and would have made the bond capital-expensive as a risk-management tool.

At the time of writing, it is known that a number of other investment banks are planning to launch new forms of mortality and longevity bond, and we anticipate rapid growth in this area over the near future.

Pension Bulk Buyout Securitizations

A final and very recent class of life securitizations are pension bulk buyouts. The most active market is in the United Kingdom, where a number of buyout funds, such as Paternoster (backed by Deutsche Bank) and Synesis Life (backed by JPMorgan) were set up in 2006 for this purpose.

Annuity books and their matching assets contain an array of risks, which bring an assortment of investment opportunities. The main matching assets for annuity liabilities are corporate and government bonds, the coupons and principal on which are used to make the payments on the annuities. The main risks on the asset side are therefore credit risk and interest rate risk. The key risks facing those paying annuities and pensions are inflation risk (since most annuities and pensions have some inflation uprating) and longevity risk. The key, as with all securitizations, is to sell off unwanted risks and retain those that the company feels most comfortable managing.

The idea behind pension bulk buyout securitizations is, therefore, for the company concerned to pay

a counterparty to take on some or all of the risks in its pension fund. One way to do so is by means of a leveraged buyout (LBO), also known as a *structured* buyout, which has been used for pension schemes in deficit where the sponsor wishes to wind up. To see how they work, consider the following example of Company ABC based in the United Kingdom:

- Value of scheme assets (A) = 100
- Scheme actuary's valuation of liabilities (L) = 120
- Deficit = 20

The company then approaches a buyout fund XYZ, which has been set up as an insurer. Suppose we have the following assessment by XYZ of ABC's pension scheme:

- XYZ's valuation of ABC's liabilities = 160
- XYZ's valuation of ABC's deficit = 60

So, XYZ's more conservative valuation of the deficit is even worse than the scheme actuary's valuation of the deficit of 20.

In the most common version of the LBO bond arrangement, XYZ offers to take on both the assets and liabilities at XYZ's valuation, subject to due diligence. XYZ also lends 60 to ABC to cover the deficit. This loan is typically at bank base rate + 1, 2, or 3% (depending on the credit rating of ABC) and must be paid off over 10 years. The assets are exchanged into a combination of fixed income and index-linked government bonds, using a combination of interest rate, duration, and inflation swaps.

As far as the company is concerned, this arrangement has the advantages of taking its pension liabilities completely off its balance sheet and replacing them by a standard fixed-term loan that everyone understands. The company also escapes the impact of FRS17 volatility on its profits (which would feed through to its reported Profit & Loss, P&L), Pension Protection Fund (PPF) levies, and asset management fees on pension assets.

For its part, the buyout fund gets a good return on its loan and, due to its size in the new issues market for government bonds, can buy the matching bonds at a discount relative to other investors. It also gains the difference of 40 in the valuation of the liabilities. In addition, by pooling the liabilities of different pension funds and buying in the relevant expertise, it can become a better manager of the mortality pool than,

say, a small annuity provider or a small company pension scheme that is unable to reap the benefits of specialized mortality expertise.

Instead of a full buyout, it is also possible to undertake many different forms of partial buyout. For example, a pension fund might use liability-driven investing (LDI) to manage liabilities out, say, 15 years but buyout liabilities above 15 years. Alternatively, it might buy out all members over 70, buy out spouses' pensions, buy out deferred pensions, or buy out level pensions in payment.

Simulation in Risk Management

Risk is a complex concept, involving the fear of things going wrong and potential associated losses. It conjures notions of real and perceived disasters, singly or in combination, resulting in large losses and possibly default on debt or bankruptcy. The nature of the potential disaster differs, of course, from one enterprise to another, from the risk of hurricanes or plant shutdowns to unexpected turns in market direction or the threat of enormous losses at the hands of rogue traders (recall Barings Bank and Long-Term Capital).

There are two components of risk, the probability of combinations of (negative) events and the magnitude of the losses resulting from these events. Both probability and magnitude could differ depending on the perception of different individuals, and in some cases, the market perceived or “risk-neutral” probabilities (*see Options and Guarantees in Life Insurance; Weather Derivatives; Mathematical Models of Credit Risk*) of events are more important than the real-world probabilities, because they drive publicly traded asset prices in the immediate term.

The Basel committee (*see Fraud in Insurance; From Basel II to Solvency II – Risk Management in the Insurance Sector; Informational Value of Corporate Issuer Credit Ratings; Compliance with Treatment Allocation*) in [1] provides a framework for regulating minimum capital requirements for banks to cover losses incurred under five different types of risk: credit risk, market risk, operational risk, liquidity risk, and legal risk, and many of these categories carry over to different types of industry as well. For banks, the most important risk is credit risk, the risk of default of a counterparty to a transaction. Of course, each of these types of risk has contributing components, and the total risk exposure of an organization is an aggregate of all the components of all five types of risk.

What are the essential features of risk? Complex structures or organizations are exposed to many different risk factors or types of risk. The probability of one or more risk events is often very small and difficult to assess for lack of historical experience. There is a relationship among risk factors that may increase the probability of them occurring

in combination and this relationship is even more difficult to assess statistically from historical data. Because of the complexity, simulation methodology is quickly becoming the method of choice for evaluating and providing safeguards against the potential losses resulting from risk exposure. Monte Carlo simulation (*see Risk Measures and Economic Capital for (Re)insurers; Reliability Optimization; Uncertainty Analysis and Dependence Modeling; Digital Governance, Hotspot Detection, and Homeland Security*) is a cost-effective method to quantify the risk of a project or investment, a generally accepted tool throughout engineering, business, operations research, statistics, and finance.

General Simulation Techniques

The first step in quantifying risk through simulation is the construction of appropriate models that strike a balance between simplicity and a close approximation of the structure of the system being analyzed. Parameters associated with statistical distributions and failure rates should, wherever possible, be calibrated to historical data. For losses due to weather or natural disaster, or to a change in market prices of publicly traded assets such as a stocks or bonds, there is considerable useful data relevant to the estimation of the model parameters underlying marginal distributions. Unfortunately, estimation of the joint distributions is more difficult. Validation of the simulation model (*see Global Warming; Hazard and Hazard Ratio*) requires checking the reasonableness of the model output by comparison with the system being modeled. The actual statistical distributions used are somewhat less important than acknowledging and modeling the uncertainties in the system in the first place. This requires the use of real-world data wherever possible to calibrate distribution parameters such as the mean and the variance.

Let us suppose that we wish to generate a random variable X , a component of the loss, with given cumulative distribution function $F(x) = P(X \leq x)$. The most general method for simulating X , increasingly useful given the general computer implementation of inverse cumulative distribution functions, is *inverse transform* (*see Copulas and Other Measures of Dependency*): generate a uniform(0, 1) random variable U and then solve the equation $F(X) = U$ for X . When X is discrete, for example, it takes

only integer values, no such solution may exist, and in this case we define X to be the smallest value of x such that $F(x) \geq U$.

With rapid increases in computer processing speed, simulation error is increasingly less of a concern. In general, standard error decreases with the square root of the number of simulations (see **Bayesian Statistics in Quantitative Risk Assessment**): if a single stochastic simulation estimates expected loss $E(L)$ with variance $\text{var}(L) = \sigma^2$ and standard deviation σ , then the average $\frac{1}{n} \sum_{i=1}^n L_i$ of n simulated (independent) values of L_i has standard error $\sigma/\sqrt{n}$. If the standard error of a single simulated estimate of risk is 100% of the value of $E(L)$, then 1 million simulations, often possible in a matter of a few seconds, will provide an estimate of the risk with relative error only around 1/10th of 1%. There is little point in more precision than this, since the error in the model or the model parameters likely contribute more than this to the total error.

Simulating VaR and TVaR

Since risk is usually identified with large losses, its measurement requires quantitative measures of the size of the right tail of the loss distribution. Suppose we have observed or are able to model the distribution of the total loss or the loss in a single unit L over a certain time horizon such as 1 day or 2 weeks. Then the *value at risk* (see **Risk Measures and Economic Capital for (Re)insurers; Solvency; Credit Scoring via Altman Z-Score; Compliance with Treatment Allocation**) is the capital required to ensure solvency with a reasonably high probability, say 95%. For a continuous distribution and $0 < p < 1$ (usually 1 or 5%), VaR_p is defined as the quantile x_p such that $P(L > x_p) = p$. In order to estimate this quantity by simulation, we can randomly generate losses $L_1, \dots, L_n$ from the model, usually by random sampling of the risk factors, and then computing the fraction of losses, $\frac{1}{n} \sum_{i=1}^n I(L_i > x)$, that exceed each threshold x where $I(A) = 1$ if the event A occurs, and 0 otherwise. We then choose a threshold such that this is approximately equal to p , i.e., solve for $\hat{x}_p$

$$\frac{1}{n} \sum_{i=1}^n I(L_i > \hat{x}_p) \simeq p \quad (1)$$

The value x_p specifies the minimum capital requirements to ensure survival with probability

$1 - p$, but it does not measure the size of those losses that exceed x_p . If the loss distribution is specified by $\bar{F}(x) = P(L > x)$ then x_p solves $\bar{F}(x_p) = p$ and the conditional distribution of losses given that they exceed x_p is $P(L > x | L > x_p) = p^{-1} \bar{F}(x)$ for $x \geq x_p$. The expected size of these (large) losses is variously called the *tail conditional expectation*, *expected shortfall*, or *tail value at risk* (see **Nonlife Loss Reserving; Asset–Liability Management for Nonlife Insurers**).

$$\text{TVaR}_p = E[L | L > x_p] = \frac{1}{p} \int_{x_p}^{\infty} \bar{F}(x) dx \quad (2)$$

On the basis of the n losses $L_1, \dots, L_n$ we can simulate TVaR_p using the average of the losses that exceed $\hat{x}_p$, i.e.,

$$\widehat{\text{TVaR}}_p = \frac{\sum_{i=1}^n L_i I(L_i > \hat{x}_p)}{p} \quad (3)$$

Of course, it is difficult to fully summarize the distribution of losses using two numbers VaR_p and TVaR_p and other moments, such as $E[L^2 | L > x_p]$, might well be considered.

For various reasons, a simulation designed to estimate VaR_p and TVaR_p may be slow or inaccurate. The probability $P(L_i > x_p)$ is typically small and may require a large number of simulations in order to obtain a reasonable number for which $L_i > x_p$. It is often possible to improve the precision of this simulation by arranging for more informative simulations in the region of interest.

Variance Reduction Techniques

These are techniques designed to decrease the variance or improve the precision of a Monte Carlo estimator by design of the simulation (see [2] or [3]). Here we discuss only a few such methods (see **Asset–Liability Management for Life Insurers; Structural Reliability**).

Suppose we are interested in estimating the expected value of some function such as $E[h(L)]$. For example, we might take $h(L) = I(L > x)$ for fixed x since estimating this quantity allows finding x_p by solving (1). Suppose we know $E[h(Z)]$ for Z under a simple closely related distribution such as the normal

distribution and it is possible to generate Z using some of the most important uniform[0, 1] random numbers U that were used in the simulation of L so that Z is highly correlated with L . The idea here is that it is often easier to estimate the (hopefully small) difference $E[h(L) - h(Z)]$ than to estimate $E[h(L)]$ in isolation. We assume that Z has a distribution sufficiently simple that $E[h(Z)]$ is known. Then we can generate random variables Z_i with the distribution of Z but closely related to L_i (for example, we could use for $Z_i = \bar{G}^{-1}(U_i)$ where $\bar{G}(x) = P(Z > x)$ and U_i is a uniform input to L_i). We can then estimate $E[h(L)]$ using

$$E[h(Z)] + \frac{1}{n} \sum_{i=1}^n [h(L_i) - h(Z_i)] \quad (4)$$

The simplest Monte Carlo estimator is

$$\frac{1}{n} \sum_{i=1}^n h(L_i) \quad (5)$$

Then if the L_i are independent, equation (5) has variance $\text{var}(h(L_1))/n$ and equation (4) has variance $\text{var}(h(L_i) - h(Z_i))/n$. The latter is an improvement if $\text{var}(h(L_i) - h(Z_i)) < \text{var}(h(L_i))$, or roughly provided that the random variables $h(L_i)$ and $h(Z_i)$ are positively correlated. Equation (4) is referred to as a *control variate* method of variance reduction. For estimation of VaR , Glasserman *et al.* [4] used the first two derivatives of the portfolio value with respect to the underlying to obtain a *delta-gamma approximation* (see **Integration of Risk Types**), and then this approximation as a control variate.

There is a similar technique called *importance sampling* (see **Bayesian Statistics in Quantitative Risk Assessment**), useful in estimating rare events or extreme quantiles as is the case in estimates of VaR and TVaR . Typically too few of our crude simulations are around the value x_p and the sample is rather noninformative of this value.

Importance sampling increases the density of sampling in the region that is most informative. For example suppose that the loss distribution has probability density function $f(x) = -\bar{F}'(x)$. Consider a random variable Z that has probability density function $g(x)$ and suppose that $g(x) > 0$ whenever $f(x) > 0$. We are interested in estimating the expected value

$E[h(L)]$, and

$$\begin{aligned} E[h(L)] &= \int h(x) f(x) dx \\ &= \int h(x) \frac{f(x)}{g(x)} g(x) dx \\ &= E \left[h(Z) \frac{f(Z)}{g(Z)} \right] \end{aligned} \quad (6)$$

This latter expected value is estimated by generating random variables $Z_1, Z_2, \dots, Z_n$ from the probability density function $g(z)$ and estimating $E[h(L)]$ by a weighted average of the values of $h(Z_i)$ of the form $\frac{1}{n} \sum_{i=1}^n h(Z_i) w_i$ where the importance weights are

$$w_i = \frac{f(Z_i)}{g(Z_i)} \quad (7)$$

The variance of equation (7) is now given by $\frac{1}{n} \text{var} \left(h(Z_1) \frac{f(Z_1)}{g(Z_1)} \right)$. We try to find an importance density $g(z)$ roughly proportional to $h(z)f(z)$ because then the variance is small. One simple device for choosing an importance distribution $g(z)$ is the *exponential tilt* of the original distribution; for example, choose

$$g(x) = \frac{e^{x\theta} f(x)}{m(\theta)} \quad (8)$$

where $m(\theta) = \int e^{x\theta} f(x) dx$ is the moment generating function of f . We are free to choose the parameter θ in an attempt to reduce the variance of equation (7), namely $n^{-1} m(\theta) \text{var} \left(h(Z_1) e^{-Z_1\theta} \right)$. In the case of estimating VaR_p , this involves adjusting θ to increase the mean $E(L)$ until the expected value of the losses is around x_p . There is an application of this technique to efficient estimation of VaR in [4] in which the importance distribution is a multivariate normal with different mean and covariance matrix, and the choice of parameters is guided by a delta-gamma approximation to the portfolio.

Simulation and Credit Risk

The term *credit risk* refers to the potential for financial loss when a counterparty to a transaction defaults (i.e., is unable to fulfill) on its obligation. An example would be when a corporation is unable to make the coupon payments on its bonds. Credit risk is perhaps the most active area of research in quantitative

finance, with new papers and books appearing virtually every week. Bielecki and Rutkowski [5] provide a comprehensive technical introduction to the subject, and the website www.defaultrisk.com provides current working papers and book reviews.

Consider a financial institution with a portfolio of N different “credits”. This could be a bank with a large number of outstanding loans or a pension fund with a large bond portfolio. Of particular importance in the modeling and assessment of credit risk is the distribution of the random variable

$$L_T = \sum_{i=1}^N I_i \quad (9)$$

where I_i is an “indicator” random variable taking on the value 1 if the i th credit defaults at or before time T , and 0 otherwise. Thus L_T represents the number of defaults up to time T in the portfolio. As defaults of different obligors are almost never independent, understanding the distribution of L_T requires an understanding of the joint distribution of $(I_1, \dots, I_N)$. We now mention a few potential approaches to modeling such a distribution.

In the *Vasicek model* (see **Credit Risk Models**) [6], it is assumed that $I_i = I(X_i > b)$, where $(X_1, \dots, X_N)$ are equicorrelated multivariate normal random variables with mean of zero. The X_i are decomposed as $X_i = \sqrt{\rho}M + \sqrt{1-\rho}Y_i$ where $M, Y_1, \dots, Y_N$ are independent standard normal random variables. M represents a *systematic factor* that is common to all obligors, while Y_i represents an *idiosyncratic factor* that is firm-specific. In this model, the asymptotic distribution (as $N \rightarrow \infty$) of $\frac{1}{N} \sum_{i=1}^N I_i$ is available and quite easy to work with. Several authors have extended this model, using the same type of decomposition, but with different distributional assumptions for M and Y_i . As the asymptotic distributions are often quite tractable in this type of model, Monte Carlo simulation is generally not required.

Another popular class of models is the so-called copula models (see **Dependent Insurance Risks; Individual Risk Models; Default Correlation; Uncertainty Analysis and Dependence Modeling** [7]). This framework begins with nonnegative random variables $\tau_1, \dots, \tau_N$ representing the default times of the individual obligors. The default indicators then take the form $I_T^i = I(\tau_i \leq T)$. The marginal distributions of the τ_i are often inferred

from market data such as bond prices and credit default swaps, and the joint distribution is modeled by choosing a particular copula, such as the Gaussian or Student- t [8]. Efficient numerical methods for evaluating quantities such as $P(L_T = k)$ are often available for copula models, so as with asymptotic factor models above Monte Carlo methods are often not necessary (see [9]).

Structural models (see **Default Risk**) attempt to link default times with the underlying “value” of a firm. They are intuitively pleasing but can be intractable or produce unrealistic predictions. A structural model assumes the firm value V_t^i follows a specific stochastic process (such as geometric Brownian motion, possibly with jumps), and defines the default time as the first passage time of the value process to some time-dependent barrier $h(t)$, which would represent some lower threshold such that the firm must default on its outstanding obligations if the value of its assets falls below this threshold. As they involve first passage times of (often high-dimensional) multivariate correlated processes, structural models are mathematically complicated, even in the simplest case of correlated geometric Brownian motion. The remainder of this section is devoted to a discussion on how to simulate multivariate default indicators $I_i = I(\tau_i \leq T)$ in the situation where the τ_i are first passage times of correlated Brownian motion. The simplest structural model for credit risk assumes that the value of a firm’s assets at any time, V_t , follows a geometric Brownian motion. The firm defaults on its debt when the asset value falls below a deterministic barrier of the form $Ke^{\lambda t}$ for the first time. This is often referred to as the *Black – Cox model*, and a comprehensive treatment is available in [5]. If $dV_t = \mu V_t dt + \sigma V_t dW_t$, then $V_t = V_0 \exp((\mu - \sigma^2/2)t + \sigma W_t)$. Assuming $V_0 > K$ it is easy to see that τ is the first passage time of W_t to the linear barrier

$$\frac{\log(K/V_0)}{\sigma} + \frac{\lambda - \mu + \sigma^2/2}{\sigma} t \quad (10)$$

For simplicity we will assume that $\lambda = \mu - \sigma^2/2$ so that τ is the first passage time of W_t to the fixed level $\log(K/V_0)/\sigma < 0$. In this restricted structural model, simulating default indicators amounts to simulating indicators of the form $I(\tau \leq T)$ where τ is the first passage time of a standard Brownian motion to a fixed negative level. Before dealing with a multifirm model, we discuss a method for simulating

the indicators $I(\tau \leq T)$. The distribution of τ is easy to simulate from and we could simulate the indicators directly. Alternatively, we could divide the interval $[0, T]$ into M equal subintervals of length $\Delta = T/M$, and simulate the values of W at the endpoints of each interval. Let these simulated values be $w_1, \dots, w_M$. Now, if $w_j < b$ for any $j = 1, \dots, M$, then clearly $I(\tau \leq T) = 1$. If we choose to set $I = 0$ if $w_j \geq b$ for each j , then we would be underestimating the crossing probability since the path may still have crossed the barrier and returned inside one of the intervals. Thus, simply setting $I = 0$ if $w_j \geq b$ for each j will not produce an accurate simulation of the indicators (we will be getting too many observations that are 0). An accurate simulation requires us to “check” if the process crossed in any of the M intervals. Conditional on the values w_j (each of which is greater than b), the probability that W crossed the barrier and returned in the j th interval is

$$p_j = \exp\left(-\frac{2(w_j - b)(w_{j-1} - b)}{\Delta}\right) \quad (11)$$

and to check if such a crossing occurred in the j th interval we simply generate a random number U and compare it to p_j . We can check each interval recursively as follows: compute p_1 and generate a random number U . If $U \leq p_1$, then W crossed the barrier. We set $I = 1$ and the simulation is complete. Otherwise we repeat the procedure for each subsequent interval until we find one where the process crossed (in which case we set $I = 1$) or we have checked each interval (in which case we conclude that the process did not cross and set $I = 0$). This will provide an exact simulation of the indicators. The Black – Cox model can be easily extended to the case of many firms whose assets are correlated by assuming that the dynamics of the i th firm’s assets are given by

$$dV_t^i = \mu_i V_t^i dt + \sigma_i V_t^i dW_t^i \quad (12)$$

where W_t^i is a standard Brownian motion and the correlation between W_t^i and W_t^j is ρ_{ij} . We will assume that the default time of the i th firm is the first hitting time of W^i to a fixed level $b_i < 0$. Recall that we are interested in the distribution of

$$L_T = \sum_{i=1}^N I(\tau_i \leq T) \quad (13)$$

and that $P(L_T = k)$ is the probability that exactly k out of N firms default. For $N = 2$ a closed form for these probabilities is available and good approximations are available for $N = 3, 4, 5$. Unfortunately for $N \geq 6$ analytic expressions are presently out of the question and Monte Carlo simulation is required. We now provide a brief outline of how the simulation would proceed. We have an N -dimensional Brownian motion (see **Insurance Pricing/Nonlife; Nonparametric Calibration of Derivatives Models**).

$\mathbf{W}_t = (W_t^1, \dots, W_t^N)$, and our assumption regarding the correlation between the components means that the covariance matrix of $\mathbf{W}_t$ is Σt , where $\Sigma_{ij} = \rho_{ij}$. The increments of this process are independent, with the covariance matrix of the increment $\mathbf{W}_t - \mathbf{W}_s$ equal to $\Sigma(t - s)$.

- Divide the interval $[0, T]$ into M subintervals of length $\Delta = T/M$.
- Generate the increments $\mathbf{Z}_j = \mathbf{W}_{j\Delta} - \mathbf{W}_{(j-1)\Delta}$ for $j = 1, \dots, M$. Note that we assume $\mathbf{W}_0 = \mathbf{0}$. This simply amounts to generating M independent multivariate normal vectors $\mathbf{Z}_1, \dots, \mathbf{Z}_M$, each with zero mean and covariance matrix $\Delta\Sigma$. Setting $\mathbf{W}_{j\Delta} = \sum_{k=1}^j \mathbf{Z}_k$, we now have an exact simulation of a “skeleton path” for our multivariate correlated Brownian motion.
- Use the algorithm described earlier to generate the value of I^i for each i . When doing so we are only using the skeleton path for the i th component, and ignoring the simulated values of $I_1, \dots, I_{i-1}$.

This algorithm would be exact if, conditional on $\mathbf{W}_\Delta, \mathbf{W}_{2\Delta}, \dots, \mathbf{W}_T$, the events “ W^i crossed in the j th interval” and “ W^k crossed in the j th interval” were independent. Unfortunately this will not be true; however, they should be *nearly* independent if Δ is chosen to be small. The smaller the Δ , the more accurate the simulation will be, and a trade-off between accuracy and computational time is required.

Simulation and Market Risk

A firm may have assets such as securities or bonds that are accurately priced in a liquid market, and market data provides substantial experience concerning the range of potential prices and losses resulting from this portfolio. The risk associated with this portfolio is often measured with quantities such as *VaR* and *TVaR*

either from a model governing the distribution of the asset prices or from historical data. When the risk measure obtains from a model, it commonly uses a normal distribution, based loosely on the assumption that for a large number of independent losses, the total loss is approximately normally distributed according to the central limit theorem. Unfortunately, defaults or large losses are often driven largely by a small number of very large nonnormal components, and in these circumstances the central limit theorem does not apply. It is probably better, therefore, to conduct a simulation from a distribution that acknowledges that the tails of the distribution may be heavier than those of the normal. This could be achieved either by using a distribution in statistics with heavier tail than the normal such as the hyperbolic model (see [10]) or by using the statistical *bootstrap*, described below.

Suppose, for example, we wish to estimate $VaR_{0.05}$ over a time horizon of 2 weeks. Also suppose we have a reasonably large database of daily returns $R_1, R_2, \dots, R_N$ obtained, for example, over the past several years. The bootstrap assumes that future returns are sufficiently like past ones so that we can draw a representative sample of 10 returns, say $R_1^*, \dots, R_{10}^*$, from the set of values $\{R_1, R_2, \dots, R_N\}$ one at a time with replacement to simulate the daily returns over the next 2 weeks, and then assume that the return for the 2-week period is the sum of these 10 draws $R_1^* + \dots + R_{10}^*$. This means that the loss over the 2-week period is $L^* = -(R_1^* + \dots + R_{10}^*)$. This process can be repeated many times to get an idea of the distribution of biweekly losses. Provided the range of returns in the original database and the value of N are sufficiently large, this distribution will typically have larger tails than the normal. The estimate of VaR or $TVaR$ is obtained from a random sample of these values of L^* as in equations (3) and (1) but with the bootstrap (see **Combining Information; Nonlife Loss Reserving; Credit Migration Matrices**).

L^* replacing the simulated L_i . An advantage of the use of the bootstrap is that it does not assume any distribution for losses, but it only assumes that the future distribution of losses is similar to that in the past. However, since daily returns are randomly sampled in the bootstrap, the validity of this method depends heavily on the assumption that daily returns are independent. This independence is, of course, invalid if some change in the economy can have a persistent effect on returns or losses over a period

of a number of days. A partial solution simply samples adjacent 10-day returns, since this incorporates possible dependence among the observations, and only requires the assumption of stationarity, but we typically need more than a few years of daily data to implement the same. An alternative is to adopt assumptions governing how the observations scale to longer time periods (see [11, Section 2.3.4]).

Operational Risk

Operational risk (see **Nonlife Insurance Markets; Availability and Maintainability; Compliance with Treatment Allocation**) includes risks due to failure of internal operations, supervisory or management relations, fraud, etc. Many of the trading risks associated with hedge funds fit within this category, because given adequate supervision and constraints, the losses could have been avoided. For example, suppose that the compensation structure in an institution rewards risk-taking behavior by increasing the portfolio and compensation of traders based on their past returns. Suppose that there is an internal attempt to risk-adjust performance measures by constraining the VaR_p of traders. Since risk profile is essentially a whole distribution and VaR_p is a single number representing it, a savvy trader will have the ability to increase risk (e.g., $TVaR$ or the higher moments of the conditional tail behavior) while keeping VaR_p constant. This additional risk will often result in additional returns, leading to increased compensation, larger portfolios, and additional incentive to increase risk subject to whatever constraints have been imposed. Similarly, supervisors have an incentive to ease up controls on their most successful traders. Ultimately, when unrestrained, market forces are directed toward increasing risk and rewards. Increasingly, supervision will require sophisticated risk measures in order to avoid undue risk. Statistical models for operational risk are discussed at length in [12] and [11, Chapter 10] and there is a comprehensive discussion of extremal events in [13]. Although many of the statistical models for individual risk factors are reasonably tractable analytically, they will often require simulation to deal with the total risk of the operation.

Liquidity and Legal Risk

Liquidity risk (see **Enterprise Risk Management (ERM); Solvency**) is the risk of losses occurring

because an asset cannot be bought or sold in a timely manner. For example, the 1993 Metallgesellschaft crisis was caused by large margin calls and an inability to unwind positions taken on futures. Risk can be modeled to some extent by modeling the time between transactions, but this must include a possible adjustment for changing market conditions. See, for example [14]. Legal risk (*see Role of Risk Communication in a Comprehensive Risk Management Approach; Environmental Risk Regulation; Operational Risk Modeling*) is risk due to uncertainty in legal actions or applicability of contracts, laws, or regulations. Information such as the fraction of contracts that are deemed illegitimate by courts, the fraction of counterparties that do not have legal capacity to enter into a transaction, the fraction of firms susceptible to copyright challenges are relevant to the construction of a suitable model. One might assume a fraction of employees are susceptible to fraudulent behavior and a fraction of supervision less vigilant than it should be, and simulate the potential losses under various scenarios.

Social Networks

Social network theory studies the formation and strength of ties among people. Early work focused on friendship ties or acquaintanceship ties, and this led to Milgram's famous rule that the average number of acquaintances linking two random people is about six (*cf.* [1]). This estimate was based on an experiment in which people tried to send mail to a stranger by relaying it through chains of acquaintances whom they believed might be "closer" to the target recipient and willing to forward it. This experiment is related to the recent *smallworld* theory, in which Milgram's relatively low number is explained in terms of most people having only local contacts, but a handful of people having very distant connections (*cf.* [2], for a review of this area).

More recently, people have become interested in networks of gene or protein interactions, or telecommunications networks, or Internet links (e.g. [3], use network methods to estimate the size of the world wide web). Scientific and commercial applications now dominate the social network field, and the traditional mathematical models (e.g., the p_1 and p^* models) do not necessarily provide very good explanation for these new situations. Additionally, much attention is now given to dynamic networks, in which new links form or disappear over time, and people join or leave the network.

The main driver for the recent renaissance in social network theory is the availability of data. Before the mid-1990s, only a few classic data sets were publicly available for analysis. However, the rise of computerized methods to automatically capture connection information, in many different contexts, as well as sophisticated new technology in bioinformatics (*see* **Microarray Analysis**) for studying relationships, have provided fresh datasets that are prompting new ideas. Additionally, the emergence of good graphic software for network visualization is an important enabler of research. GraphViz is one of the most popular freeware tools, but there are many others.

In the context of risk analysis, most of the interest in social network models pertains to either modeling the spread of contagious diseases or understanding the formation, structure, and evolution of terrorist cells. There is also some work in forensic social networks and in information networks that may find

unobvious links ("connecting the dots") in order to discover terrorist plots.

Social Network Models

Early ideas about the behavior and role of social networks were pioneered by Moreno [4], Festinger [5], and Katz [6–8]. However, modern statistical modeling was introduced by Holland and Leinhardt [9], with the p_1 model (*see* **Risk–Benefit Analysis for Environmental Applications**). The p_1 model assumes that the probability of a link *from* actor i and *to* actor j is

$$\text{logit}(p_{ij}) = \mu + \alpha_i + \beta_j + \gamma_{ij} \quad (1)$$

where $\text{logit}(x) = \ln x/(1 - x)$, μ is the average rate with which actors in this network form links, α_i is the additional rate effect due to the relative extroversion or introversion of actor i , β_j is the effect due to the relative receptivity of actor j , and γ_{ij} is the effect due to joint properties of the actors (e.g., they work for the same company, or have opposing political views).

The initial applications used data from sociological surveys of small communities, such as the Sampson Monastery Data [10]. Such real-world work suggested various extensions of the p_1 framework. Feinberg *et al.* [11] placed it squarely in the framework of log-linear models (*see* **Dose–Response Analysis; Potency Estimation; Geographic Disease Risk**), and developed a version of it that applies when there are multiple kinds of edges describing different sorts of relationships (e.g., friend, family, and coworker). They emphasized that the p_1 model is an exponential family and thus many inferential tools apply automatically. They highlight the need for developing goodness-of-fit tests, which is still an open problem in general, although in some cases the null distribution of specific model diagnostics can be calculated.

Sociological theory, coupled with experimental data, indicate that human networks are shaped by transitivity, homophily, and clustering. Much of the modern work is an effort to build models that describe these effects, none of which are captured in the p_1 model. A recent paper that surveys these ideas in the context of modern latent space models is Handcock and Raftery [12].

It is worth emphasizing that transitivity, homophily, and clustering are absent from the recent

small world research, which is driven entirely by the distribution of the numbers of acquaintances (the in-degrees and out-degrees of the vertices in the graph). This implies that some important properties of networks can be understood from very basic principles. However, sociologists would assert that human social networks require more complex models that incorporate subtle, but completely reasonable, effects.

Transitivity

Transitivity refers to the fact that if Abelard is a friend of Balthazar and Balthazar is a friend of Clytemnestra, then Abelard and Clytemnestra are likely to become friends too (this is sometimes called *triad completion*). Frank and Strauss [13] developed a characterization of the most general exponential family model for network data with binary edges. Using the Hammersley–Clifford theorem, they show that all models of this kind can be written in terms of a joint distribution defined by sets of cliques. This allows models in which the probability of edge relations depend upon whether two edges share a common actor, permitting models that show transitivity (while retaining many desirable inferential properties). The popular p^* model developed by Wasserman and Pattison [14] is within this family and transitivity has a tendency to cause clique structures, which is a special case of the observed clustering that occurs in human networks.

Transitivity appears to play a remarkable role in enforcing behavioral norms. Krackhardt [15] did experiments in which pairs of people were invited to play “prisoner’s dilemma”, (see **Group Decision; Game Theoretic Methods**) a game in which there is a large individual reward for successful betrayal and a smaller joint reward for cooperation. He found that people who were strangers and people who were friends but had no mutual friends showed similar defection rates of about 70%, but that people who were friends and had mutual friends in common were much less likely to defect (the rate was about 30%).

Homophily

Homophily describes the tendency of people to form links with others like themselves. For most social networks, edges tend to join people of similar age, income, race, and education (but for sexual networks,

they tend to join people of opposite genders, an example of heterophily). Often these demographic traits are observable covariates, and could be included in the model. Data for fitting such models used to come from studies of small communities, but new data sources are now available from e-mail records and such.

In developing models for homophily, researchers want to build models that allow increased chance of connection between similar people. For example, $\text{logit}(p_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta}$ is a trivial generalization of the p_1 model in which the vector $\mathbf{x}_{ij}$ contains covariate information on, say, the age and income of both actors, as well as indicators for whether or not the actors are of the same gender or work for the same company (as well as information on the extroversion of i and the receptivity of j). This use of covariate information allows models that boost the probability of ties between similar individuals. If the covariate information is categorical (e.g., gender or race), then one has the stochastic blockmodel proposed by Feinberg and Wasserman [16]. In general, it is hard to know when a given model is adequate; domain scientists use their best judgment about what kinds of similarities are most important.

Of course, in many applications, important covariates might not be measured. For example, although a study might record race, gender, and income, it is entirely possible that categorical variables such as political party or religious faith play an important role in the friendship structure, and these covariates might not be measured. This situation is addressed by a stochastic block model with latent (unobserved) categories, as pioneered by Anderson and Wasserman [17] and Snijders and Nowicki [18]. The model assumes that each actor has unknown category labels, and estimates these in the process of fitting the model (usually *via* Bayesian inference (see **Repairable Systems Reliability; Mathematics of Risk and Reliability: A Select History; Bayesian Statistics in Quantitative Risk Assessment; Subjective Probability**)).

Recently, latent categories have been generalized to positions in a latent space. Hoff *et al.* [19] proposed a model in which the probability of an edge from i to j is modeled as

$$\text{logit}(p_{ij}) = \mathbf{x}'_{ij}\boldsymbol{\beta} + \|\mathbf{z}_i - \mathbf{z}_j\| \quad (2)$$

where $\mathbf{x}$ is a vector of measured covariates on the actors i and j and the $\mathbf{z}_i$ and $\mathbf{z}_j$ are the positions

of actors i and j in a latent space endowed with a distance metric having norm $\|\cdot\|$. Often it is possible to estimate the relative locations of the actors in the latent space, and then interpret the dimensions of the space in meaningful ways, e.g., as degree of political liberalism or religiosity.

One issue in latent space models is the determination of the appropriate dimension; most people use two, simply because this is convenient to visualize. The norm is also up to the analyst, but the common choice is Euclidean distance. These models are typically fit from a Bayesian perspective using Markov chain Monte Carlo (*see* **Global Warming; Nonlife Loss Reserving; Reliability Demonstration; Expert Elicitation for Risk Assessment**) (*cf.* [20]).

Other Kinds of Clustering and Structure

Beyond transitivity and homophily, many networks exhibit additional cluster structure. This might be caused by the efforts of actors to balance their networks, so as to include people with specific abilities (this is reasonable for workplace friendships or terrorist cells in which piloting or bomb-making skills are needed). Also, there can be a tendency for people with many ties to accumulate other ties more quickly; the rate of increase might be proportional to the current value (this could describe a celebrity or politician). Sometimes there is special “betweenness” structure, in which one actor connects two relatively disjoint clusters (e.g., a bilingual person can connect two monolingual groups), and there is a theory that the number of social ties a person has cannot exceed about 150 (Dunbar’s number), this representing the size of a typical human tribe and the limit of cognitive ability to manage the pairwise relations among one’s connections (*cf.* [21]). This short list of examples does not exhaust the kinds of subtle effects that shape social networks; see Freeman [22] for a more detailed discussion.

However, there are two kinds of structures that merit special attention. The first concerns feedback loops; these are prominent in biological networks, but have not yet had much influence on social network models. Nonetheless, there are clearly mechanisms of this kind; often one actor will push another away if the relationship becomes too intense. Mathematical descriptions of such models will probably also need to incorporate long-term memory, which is not usually part of the biological thinking.

The second kind of structure reflects external forces. For example, in the workplace a great deal of the interaction, and much of the social network, is driven by the org-chart. People in the same division and at the same level are more likely to form ties, and more likely to compete directly. Blockmodeling allows one to partially capture some of this effect, but it would be better to have techniques that flexibly condition on specific social structures (such as org-charts or family relationships) and then use the previous techniques to study the relationships that are not already accounted for.

Counterterrorism

Social networks are becoming prominent in national security applications. From the perspective of risk analysis, people are interested in

- how social networks affect the progress of epidemics (natural or deliberate);
- how terrorist cells form, interlink, and possibly can be disconnected by strategic removal of key figures;
- how investigators can link suspects through forensic networks;
- how sets of “documents” relate to each other, and to specific people, events, or locations (this is the classic “connecting-the-dots” approach).

In the last application, text mining can be used to determine links.

However, it should be emphasized that social network methods may have been oversold. In none of these topics has there yet arisen a clear and compelling social network contribution that is of practical importance (at least in the open literature).

A second point is that many of these applications do not explicitly rely upon the mathematical models described in the previous section. Instead, they employ massive agent-based simulations. The actors are artificial, and they are assigned rules for their interactions (which may be probabilistic). The simulation then mimics the formation and dissolution of ties among them. Epstein and Axtell [23] give a provocative review of the potential scope for agent-based modeling.

Epidemic Spread

In order to assess the risk of a disease, one needs a method to estimate its consequences. For contagious disease, this implies developing models for its spread. Social network models are a tool for this purpose.

A standard example is the study of sexually transmitted diseases, such as HIV. If one understands the network of sex workers and heroin users in a community, then it becomes possible to forecast the magnitude of the public health problem and the rate at which the disease propagates through the network. In particular, it can help to gauge the impact of, say, a needle-exchange program, or find critical paths for spread, or more quickly detect the presence of a “super-spreader” who requires immediate medical treatment or counseling. A classic study of this kind examined HIV transmission among the gay and addict communities in Colorado Springs (*cf.* [24]).

Many epidemic studies use mathematical models for disease spread, such as the Reed–Frost or Kermack–McKendrick systems of coupled differential equations. However, these assume a freely mixing population, an assumption that quickly breaks down in the case of a pandemic or bioterrorist attack. One needs a procedure that accommodates self-isolation and other behavioral changes that occur. In this regard, the agent-based models are attractive; one can program the actors with rules that reflect realistic responses. This enables planners to explore the extent to which disease spread can be broken by early detection, or by closing schools and nonessential businesses, or other public health interventions. Carley *et al.* [25] is an example of agent-based modeling in the context of bioterrorism (*see* **Syndromic Surveillance; Public Health Surveillance; Digital Governance, Hotspot Detection, and Homeland Security**).

Terrorist Cells

After 9/11, social network people in federal and civilian research centers began to study the relationships among the hijackers using *post hoc* intelligence data, testimony, and background investigations. It has been suggested that this kind of work helped to identify a set of imams at mosques around the world who were recruiting disaffected young Muslims into Al-Qaeda cells. However, the evidence for his level of impact is spotty, and probably the social network research did

not add much to the connections that were discovered by intelligence analysts.

Nonetheless, the effort pointed out the kinds of things that social networks might be able to achieve someday. For example, one might be able to deduce the presence of an unknown terrorist from coordinated patterns of activity in apparently disconnected components of a network. Or one might be able to identify an actor who, if removed, would fragment the organization (*cf.* [26]). Perhaps the skill sets of the actors could indicate the kinds of terrorist activities that were planned (e.g., a genetics expert or nuclear scientist would look ominous) and from a legal standpoint, the absence of Zacarias Moussaoui from the social network of the 9/11 hijackers is intriguing.

These topics relate to inference on partially observed networks. This arises when one has

- an incomplete list of actors, so that the formation of links can be influenced by unseen relationships (e.g., a triad completion can occur without the researcher observing one of the members of the triad);
- an incomplete list of links, so that some actors might have a concealed relationship;
- one or more time periods when measurements did not occur.

Each of these three cases is a significant issue in counterterrorism. They also invoke the problem of creating models for dynamic networks, in which edges or actors change over time. So far, it appears that useful models for network dynamics have to be hand built for specific applications; general models are too vague.

An unclassified example of this kind of analysis concerns the Enron e-mail data. It was seized from the company under subpoena by the Department of Justice, and later obtained under the Freedom of Information Act for scientific research. Figure 1 shows a social network graph indicating who sent e-mail to whom. (It is too dense to read, but it illustrates the kind of visualization that can be used.)

Figure 1 is taken from Priebe *et al.* [27]. They apply the scan statistics to discover suspicious cliques, and the method extends to the time-stamped record of e-mail traffic, potentially showing how information propagates through the network within the company. Also, one could use text mining on the body of the e-mails to refine the network so that only

Figure 1 A visualization of the e-mail exchange network at Enron [Reproduced from [27]. © Springer, 2005.]

certain types of communication are displayed (e.g., exclude general all-hands memos, but include e-mails with the word "fraud").

However, the analyses of the Enron data have not discovered any fresh insights. There is a group of people who communicate to coordinate picking up their children, and an employee who changed his e-mail name, but there was nothing of legal consequence.

Forensic Networks and Connecting the Dots

A goal in network analysis is to use large databases to identify connections that can help in law enforcement

and counterterrorism. For example, one can imagine that police would someday be able to find the closest person in a murder victim's social network who owns a handgun, or who has a previous arrest for violent crime.

These applications would require software that enables investigators to troll through large, unstructured databases to build the social network, and then explore the links in an expanding neighborhood. Such large databases are already emerging; ChoicePoint and LexisNexis/Seisint are data marts that are currently used mostly for checking credit history, but they have subsumed many public datasets and

have the potential to support estimation of the social network surrounding an individual.

Similarly, the FBI now maintains DNA samples on a great many criminals. It is likely that with appropriate technology, a blood sample at a crime scene might be identifiable as coming from someone who is, say, a probable cousin of Tony Soprano and a matrilineal relative of Dr Melfi, even if the unknown perpetrator is not in the FBI database. A simple form of this technique was used to arrest Dennis Rader, the BTK strangler; his daughter's DNA showed a close, but not exact, match to archived evidence from the crime scenes.

These examples are special cases of the larger problem of connecting dots in seemingly disparate information sources. Abstractly, analysts would like the capability to text mine documents, phone call transcripts, commercial transaction records, and police reports in order to find threads of meaning that link clusters of records in sinister ways. The visionaries who propose this hope that social network methods may someday be supple enough to support automatic or semiautomatic research of this kind.

Societal Decision Making

Decision and risk analyses are commonly used in the public sector to support major decisions relating to many issues including societal risks. If a potential development has significant risks to health, society in general, or the environment, not only is there a clear imperative to examine and weigh the issues in careful detail, but also an imperative to do so openly, as in the case of a broad range of western democracies. There is a need for auditable decision processes, both to show stakeholders that their concerns have been explicitly addressed even if not resolved to their entire satisfaction, and to demonstrate that good governance practices have been observed. For this reason, quantitative decision analyses have a long history in the public sector [1–3].

As we remarked in the article on decision analysis (*see* **Decision Modeling**), there is no commonly agreed methodology for the quantitative support of decision making. Here, we contrast the following two in relation to societal decision making: (Bayesian) decision analysis based upon the subjective expected utility model (*see* **Subjective Expected Utility**) and cost–benefit analysis (*see* **Cost-Effectiveness Analysis**), noting that other methodologies have also been used [4, 5]. We shall also note how they may be deployed in modern democracies, the role of regulators, and the growing role of public participation.

Cost–Benefit Analysis *versus* Decision Analysis

For many years, the most common type of analysis used to support societal decision making was cost–benefit analysis [1, 6, 7]. In fact, there is no single cost–benefit methodology but a family of methods sharing a common approach – namely, the value of a decision equals net expected benefits minus net expected costs, both expressed monetarily. The aims of cost–benefit approaches are laudable. They seek to present an analysis of potential courses of action and their monetary worth to a (large) group of people, often society in general; and by using money as a common measure, they seek to do so in an agreed objective fashion. However, the difficulty is that monetary worth is essentially a subjective judgment. Two individuals need not agree on the monetary worth of

an item or impact; and, indeed, they seldom do. Thus, in seeking to present a single monetary valuation of any course of action, cost–benefit analysis is ensuring that at its heart is an ill-defined concept. It begs controversy in assuming agreement and unanimity when it is virtually certain that there is none.

In contrast, decision analysis explicitly focuses on the individual and, in doing so, allows different individual perspectives to be compared and explored, supporting and articulating debate. Often, differences between individuals are reflected in the weights that they place upon different factors or in the likelihood of some event. By a careful use of sensitivity techniques [8], an analysis can identify which differences are key and thus focus debate on the issues that matter. It can often be shown that despite differences in judgments, many elements of society agree on the course of action, thus diffusing sterile debate. For this reason, decision analytic approaches have been gradually superseding cost–benefit ones, although some see this more as a convergence of paradigms than a shift from one to another [6, 9].

Democracy

In modern democracies, the context for such decision analyses is complex. An “Athenian” view of democracy might suggest that all members of society have an input into all societal decision making, but such direct or deliberative democracies are clearly infeasible in the modern world and did not really exist in classical times [10]. Also, as Arrow has shown, direct democracy is an ill-defined, unachievable concept [11, 12] (*see* **Group Decision**). Thus, modern democracies are constructed around representation, with politicians being elected to run the state, perhaps informed by occasional referenda. In many cases, they delegate societal decision making to regulators and planning agencies, e.g., the US food and drug administration (US FDA) or British health and safety executive (HSE). Modern societies are a complex weave of agencies and bodies with differing remits and powers of decision making overseen by national and local political assemblies and, perhaps, by an independent judiciary. And this, of course, is an ideal(!), in Politics politics are rife and decision making can sidestep some of the formal procedures, driven by other agendas and horse trading. Against this background, there is an overwhelming need for

analytic methodologies, which document explicitly the reasoning behind any decision, indicating the evidence and how it was weighed in reaching the decision.

Stakeholder Involvement and Public Participation

Societies are not static – they evolve. Modern Western democracies are suffering from a “democratic deficit” and growing public disillusionment with current, purely representational processes. Pressure groups are demanding a louder voice and a greater input for their particular stakeholder perspective into the shaping of society. This is leading to a move toward more public participation and a greater involvement of stakeholders [13–16] (*see Public Participation*). The use of mechanisms, such as stakeholder workshops, citizens’ juries, and on-line deliberation is emphasizing the need for analytical techniques to be transparent and available to a much wider audience than it was previously. If analysis is to inform debate – and surely that must be its purpose – then it must be easily understood by all the participants. Sensitivity analysis can help here, allowing different parties to the debate to see how their perspectives and judgment affect the conclusions and where they stand relative to other participants [8]. A careful use of sensitivity techniques can identify which differences are key and thus focus debate on the issues that matter. It can often be shown that despite differences in judgments, many elements of society agree on the course of action, thus diffusing sterile debate.

Discussion

A successful decision or risk analysis to support a societal decision must recognize the imperatives arising from the political context. It must recognize the different institutions involved and their statutory responsibilities, the different players involved (*see Players in a Decision*), and the need to communicate the analysis to each of these. It must seek to articulate and inform debate, explicitly demonstrating how different evidence and perspectives affect the conclusions. All this means that conducting risk and decision analyses requires many skills beyond the purely technical ones – process, communication, and

interaction are as important as the ability to model and calculate.

Software Testing and Reliability

Today computers and software are all pervasive and increasingly an important part of most systems; the latter includes embedded systems (as may be present in medical devices, airplanes, or cars), systems involving people working in harmony with computers (for instance, in air-traffic control), and so on. From the perspective of quantifying risk, it is often necessary to have some measure of the “goodness” of any associated software. This is typically captured in the concept of *software reliability*. See [1], for instance.

Of course, reliability is usually expressed as the probability of error in a particular situation and over a prescribed period of time. In some sense it is concerned with measuring the trust that can be placed in a given system. This is the basis for the definition of software reliability.

Software reliability is the probability that a piece of software continues to perform a particular function over a particular period of time and under stated conditions.

In software terms, reliability is a difficult concept. If a piece of software is executed in the same environment and with the same data then it will always behave in exactly the same way. So what is this concept of reliability? How should it be interpreted? The key is to consider software running with a variety of different sets of data and perhaps under different sets of conditions. The variations in input and environment serve to create a domain within which it makes sense to discuss reliability. It is then assumed that elements of this domain are selected at random and with equal probability. The measure of reliability of software is not necessarily static; in the context of computing and software systems, it can and often does change with time.

It is important to draw attention to related issues of safety, security, etc. In these high-integrity systems, reliability is the most important consideration. But reliability theory itself does not take into account the consequences of a failure. High-integrity considerations must take account of what happens in the event of software failing; reliability considerations, typically, do not address these. See [2] for further information.

Software Testing

In terms of achieving the desirable goal of being able to guarantee the reliability of software, the activity of testing that software is crucial. In general terms, the more effective this process is, the higher the likelihood that the software will achieve desirable levels of reliability.

The basic objective of software testing is to uncover faults in the software, typically by attempting to cause failure of the software or by showing that the software fails to meet its requirements. The faults should then be removed, leading hopefully to improved reliability of that software. For the purpose of testing the software, it is necessary to have a clear statement about the intended effect of a piece of code; both functional requirements and nonfunctional requirements need to be clearly stated. Testing will typically show the presence of errors but not their absence.

There are additional important objectives to testing. These generally relate to the considerations of the overall quality of software and software process. They emerge from considerations related to the careful planning and management of the testing process. For, in general, the testing process will require the selection of a suite of test cases and questions will naturally arise about the effectiveness of the particular choices. Thus, measuring the number and the type of errors provides measure of the efficiency of the testing process, as well as messages about the nature of defects and the effectiveness of the software development regime; monitoring the trends in terms of the failures over time can provide an indication of reliability of the software; monitoring the arrival of defect reports from clients provides an indication of the readiness of the software for release; and so on.

The scope of testing is considerable and there are many important aspects to it. Apart from checking that results are as expected, there is checking to obtain or ensure some measure of reliability, there is testing for security (e.g., of firewall software), testing for performance (e.g., timing), testing to ensure safety – which can be vital in safety-critical or other forms of high-integrity software, and so on. The choice of tests is often nontrivial and should be guided by a careful strategy incorporated within a test plan. For instance, ensuring some measure of independence between different tests may be an important feature to encourage efficiency in the testing process, retaining

tests so that they can be replayed quickly is likely to be important for large systems, and so on.

Within the range of techniques that can be applied for the purposes of testing a particular program, a range of checks can be performed:

Static checks are carried out on code without running or executing it. The checks include, for instance, whether the code exhibits syntax errors or type-checking errors, whether it compiles, etc. Checking on adherence to programming standards – an activity that may utilize information about metrics – also falls within the realms of static checks.

Dynamic checks necessitate running or executing the code. They include matters such as checking that the output is as expected, performance requirements are met with, run-time errors do not occur, etc.

The terms *verification* and *validation* are complementary and describe general approaches to dealing with aspects of the testing of software. Basically they refer to those activities that are used to ensure that the software product is being built correctly and corresponds to the needs and desires of the customer.

Formal verification is defined as the application of mathematical techniques and mathematical argument whose purpose is to demonstrate the consistency between a program and its specification.

Informal verification is defined as the process of determining whether the products of a given phase of the software development cycle fulfill the requirements established during the previous phase.

Validation is defined as the process of evaluating software at the end of the software development process to ensure compliance with software requirements.

Of the above, formal verification is somewhat mathematical (see [3, 4]) but it offers interesting insights into the nature and the structure of programs.

Testing, validation, and verification can typically be applied to all stages of the software life cycle. There is a general rule that the earlier an error is caught the better it is. This is important for productivity, cost, and quality, and as such impinges on the morale of software engineers. For success, typically, it is better to have a more formal approach; here “formal” is intended to convey a carefully thought out and disciplined approach that may or may not entail mathematics.

All validation and verification activities should, if possible, be carried out by a team independent of the one undertaking the development of the software.

In this way, problems arising from preconceived notions, ideas, or assumptions tend to be addressed. Verification has the capacity to overcome some of the limitations of testing.

Testing should not be an afterthought; it should be planned and addressed at all stages of the software life cycle:

- **Requirements stage**

Initial test cases must be generated from the specification and these need to be accompanied by the expected outcome; these can also be retained for final testing. The consequences of requirements (which ought to be testable) must be investigated. When this is being performed, the general testing strategy for the final product can be developed and this will include verification requirements, test schedule, milestones, and analyses.

- **Architectural design stage**

Plans for test configurations and integration testing are established. Verification requirements are expanded to include and highlight individual tests.

- **Detailed design stage**

Test data and procedures should be devised to exercise the functions introduced at this stage.

- **Construction stage**

Static analysis tools can be used for detecting code anomalies, identifying unreachable paths, collecting metrics, etc. Dynamic analysis tools are used for testing performance. Informal testing of individual modules may take place at this stage.

- **Operation and maintenance**

Fifty percent of the life cycle is typically involved in this activity. Careful management of tests and the results of tests will reduce the necessary effort here and enable subsequent tests to be carried out more efficiently. For example, after modification, only those modules that have been changed may need testing; regression testing (see below) involves performing some or all of the previous tests to ensure that no errors have been introduced; usually this process is automated with previous results having been retained for easy checking.

For certain phases of the life cycle – especially the earlier ones – technical reviews are often used. These typically take the form of walk-throughs or

inspections with a group of experts analyzing documents such as specifications, designs, etc., for quality attributes (e.g., completeness, consistency, etc.). For guidelines on the conduct of technical reviews, see [1].

Different Approaches

A wide variety of different approaches exist, some being relevant to particular stages of the life cycle. We highlight the main approaches.

Functional Testing

Functional testing (*see Reliability Data; Human Reliability Assessment; Fault Detection and Diagnosis*) – also called *black box testing* – is concerned with testing the developed software against its stated functional requirements. The technique is also used to validate the performance and behavioral requirements of the final, integrated system. Test data is derived from the specification without reference to the internal structure of the code. Implementation details are not considered. The specification will typically be described precisely in natural language, using a model-based notation such as Z or vienna development method (VDM), or using an algebraic or axiomatic notation. In all these cases, certain inputs can be chosen and the specification will identify the expected output. The types of errors typically found include identifying incorrect or missing functionality, interface errors, data manipulation errors, performance errors, and start-up and shut-down errors.

To improve the rigor and coverage of functional testing, several techniques that aim to ensure optimal usage of the testing effort can be employed. These include the following:

- **Equivalence partitioning**
Here the test data for the program is partitioned into a small number of equivalence classes on the basis of description or specification. Then test selected representative members of each class, and view these as representative of the class as a whole.
- **Boundary value analysis** (*see Potency Estimation*)
Often software fails at the boundaries, e.g., 0, 1, *nil*. Test data is typically selected on the basis of this (*see Potency Estimation*).

- **Cause–effect graphing**

The input/output domain is partitioned into various classes, each of which produces a particular effect. For instance, a user issues a particular command, a particular message is received by the system, a sensor provides certain information, and so on. This is typically used to derive test cases, each of which exercises a particular possibility.

- **Comparison testing**

When there are different implementations of a particular task, the same test can be applied to each version and then errors are indicated by different outputs from two or more versions. This is especially relevant in the context of N-version programming, for instance.

- **Grammar-based testing**

Here the input is described by means of a grammar and testing is then based on exercising all possible combinations of alternatives within the grammar. In such cases, automatic methods can be used to ensure coverage of the range of possibilities. This is particularly relevant for compilers and other syntax directed tools.

Structural Testing

Alternatively called *white box* testing, this approach takes the structure of code into account. Test cases are chosen so that, for instance,

- all independent paths through a program are tested; this leads to considerations about the effectiveness of testing in terms of path coverage;
- all statements in a program are executed, and hence leads to considerations about statement coverage.

Typically, logic and design errors are identified, often because they are on paths not accessed by functional testing; note that infeasible paths may exist, and it may not be possible to exercise certain statements. In addition, erroneous output, performance violation, exception raising, etc., are all addressed.

To allow the testing of partially complete software, devices such as stubs can be used; to prevent catastrophes from erroneous software, test harnesses can be used; and simulated environments often have a role to play.

Controlling Complexity

The complexity of the testing process is typically controlled by testing units individually; hence this is

called *unit testing*. *Integration testing* (see **Repeated Measures Analyses; No Fault Found**) is then performed by gradually combining units to form larger and larger entities and testing them. Eventually, an entire system is tested. These considerations give rise, naturally, to the following:

- **Integration testing**

This involves integrating and testing parts of, and eventually, the whole system: here, checks are made on matters such as functions being defined, interface compatibility, e.g., whether parameters are appropriate, and so on. Both bottom-up and top-down approaches are possible. This depends on careful structuring of the code with careful testing of modules, and then testing of interfaces between modules. In the particular case of object oriented programming, integration testing leads to testing of classes, then classes that tend to cooperate, and so on.

- **System testing**

Here test cases should be selected from an input population, which reflects the intended usage of the software; for safety-critical software, the software must be tested in situations where correct functioning is critical; reliability estimation is typically needed and this is often done using statistical testing techniques.

- **Acceptance testing**

This happens with the customer prior to the software being released to the customer.

- **Regression testing**

In many areas of software development it is desirable to retest software to ensure the absence of new errors and usually enhanced reliability. In particular, this should happen on completion of maintenance activity. Ideally, the whole process of retesting should be automated as far as possible, e.g., rerun various tests. Regression testing addresses this. To accomplish it, typically there is a need for careful management of all test information, for the use of stubs and drivers, for harnesses within which to carry out tests, and so on. All these entities ought to be brought under control of a configuration management and version control regime.

- **Performance testing**

Especially in areas such as real-time systems, safety systems, security systems, etc., there is a need to test the performance of software. Thus,

much of whether it meets stringent timing requirements even in situations of stress will depend on the criticality of the software, but considerations of worst possible scenarios are often used to guarantee levels of performance. Such matters, of course, must typically be considered when the software is being designed. For, an error in one piece of software can contaminate another piece of software and so isolating the software in particular machines can help in resolving certain difficult situations.

In some cases software systems can continue to operate in a degraded state, e.g., because of some failed component (software or hardware). In such cases it is important to carry out rigorous testing of the degraded state to ensure that it does perform to the expected standards.

Different Testing Scenarios

In the broad spectrum of testing, there are many levels of complexity. Testing simple programs that begin, execute, and halt is relatively straightforward. For testing programs that retain some memory from previous data, two possible approaches are apparent: choose input and internal state randomly; alternatively reinitialize each time and use a sequence of inputs for each test case. For testing real-time programs, each input is typically a stream of values; difficulties occur if long periods of operation are typical, in which case steps are taken to curtail testing time while remaining realistic. For safety-critical system testing, criteria remain the same as above but choice of inputs and therefore tests must cause the system to become active and critical.

It has been estimated that high-rate errors (i.e., those that occur most frequently when a system is being used) account for nearly two-thirds of software failures reported by users. By concentrating the testing effort on those parts of the software that are anticipated to be invoked most frequently during usage, these failures can be identified and removed first.

Statistical Testing. It is often the case that certain inputs to software can be expected to occur more often than others. In general, a frequency distribution or *operational profile* (see **Reliability Integrated Engineering Using Physics of Failure**) can be used to describe the expected frequencies with which certain inputs can occur, and these capture the patterns

of use. In practice, deriving an accurate operational profile is not always straightforward, yet can be accumulated over time by monitoring use. Alternatively, estimates can be derived from requirements, interviews with users, marketing studies, and other such user-centered sources.

Statistical testing involves testing software according to the way in which users intend to use it. It focuses on the external behavior of the entire integrated system and ignores internal structure. The intention is to uncover problems with the states that are likely to occur most frequently or to test more thoroughly those parts of the system that are likely to cause most damage. So an important purpose of statistical testing is to provide measures or estimates of the reliability of software. In the normal way, failure data can be collected and used to estimate the reliability of the software system.

Error Guessing. One of the major problems with software is that many faults do not become apparent until a certain combination of events results in an incorrect state during execution and a failure occurs. Owing to the complex nature of software systems, it is usually not viable to test every possible combination of events and therefore it is possible to miss such erroneous states. Yet, providing guesses of such combinations (as well as other such possibilities) can often be effective in terms of identifying fault situations.

Checklists. For certain kinds of systems, e.g., evaluating a human–computer interface, certain tests or checks reflecting accumulated best practice can be captured in checklists.

Testing and Safety-Critical Systems. In the case of safety-critical (*see Systems Reliability; Reliability Data; Human Reliability Assessment*) and other high-integrity software, guarantees typically need to be provided about measures of reliability (as well as safety, etc.). Modeling reliability growth and trends over time and during the continual evolution of the software is one approach. But effective approaches based on Bayesian statistics are emerging to demonstrate that the probability of failure is very low (*see* [5]). These studies provide additional pointers to choices of test cases.

Assessment of Testing Methods

Most methods are heuristic and lack a sound basis and intuitive ideas about the patterns of usage of

software (e.g., which functions will be invoked most frequently) are often inaccurate.

Functional and structural testing approaches are typically seen as complementary, rather than alternative, to each other. They uncover different types of errors. Likewise, performance testing is again complementary to these. So there is an onus on devising a cocktail of approaches to testing that in some sense is minimal and yet seeks to test and exercise the software in realistic and meaningful ways.

In employing the various testing methods, it is customary to develop a suite of tests. This might deal with separate classes in equivalence partitioning or separate routes through a program. When the various tests are viewed as a collection, it is possible to talk about the adequacy of that collection. For example, the issues could be what percentage of the possible equivalence classes and what percentage of the routes through a program have been tested. These considerations lead to measures of the *adequacy* of the various forms of testing. A good overview of the issues is contained in [6]. But it is not uncommon to seek 100% path coverage and around 80–90% statement coverage.

Mutation Testing. It is important to obtain some feeling for the number of faults in a program on the basis of an analysis of the outcome of testing.

Mutation analysis – seeding faults – can be used to assess the effectiveness of testing methods. This is usually accomplished by seeding or inserting faults into the software and basing analysis of the effectiveness of testing on the ability of the tests to discover the seeded faults. Typical examples are replacing + instead of –, or > instead of >=, for instance.

Mutation testing involves making changes of this kind (temporarily) to the program, running it with the same previously used test data, and then checking the final results.

If these results are the same as those before the errors were introduced, then some investigation is called for.

Test Planning

There are many ways in which software can be tested, the choice being dependent on characteristics such as the size, criticality, and complexity of the system as well as specific customer requirements. Careful test

planning is needed to maximize the coverage and reap the benefits of the testing activity.

In this it is important to remember the mutual dependencies and contributions of all the various components – hardware, system software, compilers and other tools, devices, etc. In all testing scenarios, the choice of inputs must be representative of the intended usage of the system.

Planning testing is typically important. It is desirable to be comprehensive on the one hand, and yet efficient and effective on the other. So tests should be chosen with care in such a way that they do not duplicate previous tests, but rather they explore some novel feature of the software.

In planning testing, much depends on the criticality of the application. But it is typically desirable to include black box testing and white box testing, and to proceed using unit testing, integration testing and system testing taking into account testing of any performance issues, testing usability and performance as well as testing of the user interface. In carrying out these considerations about the adequacy of test, coverage needs to be taken into account; ideally aim to have 100% coverage of equivalence classes, routes through a program, and so on. In addition, data verification and software performance modeling are frequently practiced.

Software Reliability Modeling

A model of reliability *versus* time can be obtained for a software product by measuring certain trends over the time during which the software is evolving. These can be plotted to produce a graph, for instance. Extrapolating is then one means to predict the future reliability of software. Failure data – possibly generated by tests, and followed by the use of statistical testing is relevant – are used to model current behavior and then statistical inference may be used to predict behavior at a specified time in the future. The problem is to decide which model provides a close enough picture of reality to give accurate results.

The purpose of reliability modeling is to predict reliability; current failure data is collected and used to infer future behavior. This is typically done by finding some mathematical means of capturing behavior and then using mathematical and statistical techniques to provide answers to common questions. Examples of the use of such predictions include the following:

determine at what point in time a particular level of reliability will be reached; or, determine what level of reliability will have been reached by a certain point in time.

Several models have been developed. However, these have tended to give often largely different results for the same data sets. An appropriate model must be selected according to the circumstances and the context, and a certain amount of judgment must be used to determine which model gives the best results.

The Logarithmic Poisson Model. In this model, initial modeling of failures is conducted with respect to execution time, that is, the actual processing time of the software on the computer. This can then be translated into calendar time, which humans experience. Calendar time is more useful to software engineers and managers in terms of predicting cost, schedule, and resources.

In certain applications of reliability theory it is customary to assume a constant failure rate. Then the reliability R can typically be expressed in the form

$$R = e^{-\lambda t} = e^{-t/T} \quad (1)$$

where T is mean time between failures, or λ is mean time to failure, whichever is most appropriate in the circumstances. Such a model, assuming the parameters are known, can then be used to predict reliability at some point in the future or conversely predict a time at which a certain level of reliability can be expected. In the context of software, the basic assumption of constant failure rate is unrealistic.

Jelinski–Moranda model

The basic Jelinski–Moranda model (see [7]) has been extended by Musa (see [8]). This is based on the notion that if a software contains n faults, then each of these faults contributes equally to failures; moreover the repairs done to remove faults are assumed to be perfect and, in particular, they do not introduce further faults. There is plenty of evidence to support the view that some of the assumptions here are quite unrealistic. Nevertheless, the model is fairly commonly used.

Littlewood Model. This model (see [9]) is based on the idea that the nature of the contribution from the individual faults to the reliability profile is random. A consequence of this is that the effect of removing

a fault will be unpredictable and dependent on the particular fault.

Again, since the effect of faults is unpredictable, there is something little unrealistic about the basic assumptions underlying this model.

Other Models. For a review of other models of reliability, see [10].

Static and Dynamic Analysis

Static Analysis Techniques

Static analysis is a process that involves analyzing software products without actually performing execution. Static analysis techniques have been applied mainly to source code, although it is possible to analyze other products (if these are expressed in formal or semiformal notation). Specifications, designs, and fault trees, for instance, all represent possible descriptions of a system and are hence valid for analysis. However, the analysis of source code is the most important target for analysis because this is ultimately what determines the behavior of the system.

In the course of this, data is collected and typically this relates to various aspects of the structure, complexity, size, and other internal attributes of the software. Since the code is not executed, issues involving the operational environment are not addressed.

Manual approaches to such analysis and data collection tend to be error prone, time consuming, mundane, and difficult to replicate. So automated software support is typically used. Such tools can greatly increase the efficacy of the static analysis process.

Static analysis can involve different levels of complexity and can be performed for different objectives. For example, it can be used to uncover faults in software, evaluate the quality of code, demonstrate that a module meets its specification, or prove the correctness of an algorithm. These activities may be performed at different stages of the life cycle.

One way in which a program can be shown to conform to its specification is known as *symbolic execution*. This involves deriving a symbolic expression for each variable from the code that affects it. The resulting expression can then be checked against the expected expression from the specification.

Some of the tasks that can be performed during static analysis include the following: detect anomalies, for instance, variables have been defined but

not used, variables have not been initialized, non-portable language features have been used, e.g., use of a particular language feature; apply certain techniques to derive *metrics* that can be used to draw conclusions about the quality of code; ensure coding standards have been adhered to (e.g., guidelines on module size, comment density, or the use of GOTO); check adherence to programming standards (e.g., the rules of structured programming); prove that software conforms to its specification (verification).

Metrics related to software structure are often defined on abstract models of the software rather than on the software itself. *Call graphs* and *control flow graphs* are examples of such models.

A *call graph* is a graphical representation of the interactions that exist between a set of modules. Examples of metrics that can be derived from a call graph include the number of recursive modules, hierarchical complexity (number of modules on each level of the graph), testability measures, and the average number of calls per module as well as highlighting calls that have not been invoked.

A *control flow graph* is a graphical representation of the algorithmic structure of a module. That is, it depicts the flow of control from the entry point to the exit point of the module. Metrics that can be derived from the control flow graph include the number of nodes, number of edges, the depth of nesting, and adherence to structured programming rules. This also highlights the paths that have not been tested, e.g., unreachable paths, as well as poorly structured or “spaghetti code”.

Possibilities for more detailed forms of analysis also exist; but methods such as formal proof are often hindered by the lack of formal software development in industry and suitable verification systems.

In general, there is a lack of standards in the area, which means that objectives are often unclear and benefits are difficult to quantify. Moreover, some language features (such as the aliasing of variables and the use of pointers for parameter passing in C) cause inherent problems for analysis tools. It is possible to subsume some forms of static analysis into the language and compiler. Certain advances even suggest the incorporation of more detailed forms of analysis, such as proof of code against its specification, but this would require rigorous specification and design information. This must be taken into account early in the life cycle.

Tools for static analysis typically exhibit an architecture that typically involves a front end that collects data from specific languages and expresses it in a general notation and a back end that performs calculations on data and displays results. The output can typically be in the form of metrics, graphs, or text. But generally tools tend to vary in scope and applicability. It has been observed that metrics may be defined differently for different languages and across different tools.

Dynamic Analysis

Dynamic analysis can be viewed as a means of collecting and analyzing data about the software during the testing activity. Dynamic analysis techniques that require extra instructions to be inserted into the code are called *intrusive*. *Nonintrusive* analysis usually involves running the analyzer on a separate system or environment.

Dynamic analysis involves analyzing software and in so doing using the results of execution. The software must be executed according to its intended usage. This can take various possible forms:

- **Program instrumentation**

This involves inserting various kinds of *probes* into the code to provide a profile of execution – for example, coverage analysis – statement counters are used to determine path or statement coverage by test data; dynamic assertions – predicates concerning values of variables that must hold at a certain point are inserted.

Inserting probes may increase the size of the code significantly, leading to problems, especially in real-time systems.

- **Failure analysis**

An important, though obvious, approach is the collection of failure data for the executing software system. This can be used in reliability estimation.

- **Performance characteristics**

Dynamic analysis is also concerned with the performance characteristics of software such as response times and resource usage.

As with static analysis, the facility and efficiency with which dynamic analysis can be carried out is enhanced dramatically through the use of good support tools.

Tools Development

A range of tools can be used for static and dynamic analysis and they vary in their capability. As expected, static analysis tools are concerned with static analysis of source code and certain facilities based on the same; dynamic analysis tools are based on testing and the conclusions that can be drawn from the test. On occasion, both sets of facilities can be found within one tool.

Typically the main objective of static-analysis-based tools is to provide an evaluation of the quality of a developed software system. A front end may accommodate different languages (e.g., Ada, C, Pascal) but the back end will be similar for each. But typically code is the only product analyzed. Metrics of various kinds can be gathered automatically. Possible metrics include the following:

- **Metrics gathering**

A range of metrics can be gathered automatically. These are related to various aspects of the software such as size, structure, complexity, and documentation. The possibilities are many but, for instance, these could include the number of statements, program length, number of noncyclic paths, number of jumps, comments frequency, average statement size, and number of input/output points. Experience will tell that, for good quality programs, these various metrics should normally lie within a particular range, the latter being defined by a low value and a high value.

The visual display of metrics data allows them to be comprehended more easily and areas for attention to be identified. The concept of a Kiviat diagram or graph is often used; this provides two concentric ellipses, the outer one defined by the high values of a range, and the inner one defined by the lower values. Then when actual values are plotted, they all ought to lie between the two ellipses. Any failure to do so is highlighted. This allows the results for different metrics to be compared, as well as describing which values are beyond their limits.

- **Classification analysis**

On the basis of ranges as defined by the low and the high levels, conclusions can be reached about different sections of the code. To be precise, different sections may be classified as acceptable, readable, testable, or self-describing, thus

implying something about the existence of commentary of some kind. And other parts may be flagged as unusual or worthy of further scrutiny.

- **Quality factor indicator**

On the basis of above classification, sections of the code can be categorized and a report produced automatically. This can identify good sections of code and also sections that merit further attention.

Typically, e.g., in the form of a pie chart, a report can be produced showing the distribution of components according to their quality factor. For instance, a report might indicate that, of the existing modules, about 69% were accepted and about 10% required further documentation. A list of modules that make up each percentage can then be obtained.

Such reports are useful as a management tool to control activity. This is often known as *management by metrics*.

Dynamic analysis can take place during the testing phase to supplement this activity, or by rerunning the test cases and thus simulating the activity. The latter method is used when the product is being evaluated, for example, for efficiency or reliability, by an independent body.

Toward Reliable Software

A whole host of factors contribute toward the desirable goal of achieving reliable software. Included in these is a set of consideration such as

- capturing the role that the software has to play in precise detail, i.e., its functionality, and importantly, also the considerations such as performance;
- protecting the software from interference from elsewhere, e.g., from malicious software such as viruses but also from deviant behavior of other software in the vicinity (which may contaminate, for instance);
- adopting certain approaches to design, e.g., those associated with human–computer interface considerations and these in turn may be associated with human conditions such as color blindness, or the requirement that no single error should bring the system to a dangerous state; there are design techniques in software engineering that accommodate such considerations;

- recognizing the role of certain software process issues, e.g., choosing a compiler or software tool of high quality.

Yet despite best endeavors with respect to the design of software and its testing, it is recognized that faults may still remain in software. Software fault tolerance techniques exist to provide another additional kind of approach.

Software Fault Tolerance

There are various approaches to software fault tolerance.

Exception Handling. Typically, as a result of execution of a program some fault occurs; in many modern languages (e.g., Java, Ada) this causes a flag or *exception* to be raised. Examples of exceptions are division by zero, arithmetic overflow, certain kinds of inappropriate input, etc.

There is also the potential for the fault to be handled either at the component level or at the system level as appropriate. The “repair” (to the system state, *not* the program) is dealt with by an *exception handler* – a piece of code to which control is passed, and which is then executed prior to control returning to the main program sequence. Normally, exception handling is done by that designer who is most likely to understand the ramifications of an exception being raised. To illustrate, if an erroneous piece of data is passed to a component, this is likely to be handled at the system level; or, if an arithmetic error leading to overflow occurs in a component, it is likely to be handled at the component level.

N-Version programming. N-version programming (also known as *diverse programming*) involves a variety of N ideally independently and diversely produced routines satisfying the same specification being written in isolation from one another. Though this is the principle, achieving design diversity in practice is not always straightforward; see [11]. When a result is sought, voting takes place and broadly speaking, the result gaining most votes is the answer delivered.

There are different strategies for choosing N and for deciding how the voting should proceed. For instance, a system may be deemed to operate satisfactorily if at least three out of five components agree. Typically $N \geq 3$, although $N = 2$ is sometimes used

for systems such as railway signaling systems; in the event of disagreement in such systems, a fail-safe situation needs to be established, e.g., all the trains stop.

Voting typically has the effect of masking single faults. If $N \geq 5$ there is the potential to mask more than one fault. So voting provides adjudication and has the capacity to detect errors. Indeed, the behavior of individual components can be monitored and a judicious approach to replacing unreliable components by more reliable components can lead to ever more reliable overall systems. This same strategy can also be used to gradually introduce new technologies and new developments in a controlled manner by monitoring their performance.

Possible damage caused by faulty software must be limited and must not extend to other versions. So these should not affect global variables, e.g., run each version on a separate processor if necessary. Recovery is effectively achieved by ignoring a version.

Voting must be simple (e.g., majority) and ideally exact. The situation is often complex. If real numbers are involved, then rounding errors may be present. Then inexact voting results, and this increases complexity. If large arrays are involved, that can be time consuming and can lead to problems of performance. And, of course, programs can fail by giving the wrong result, looping indefinitely, failing to achieve performance targets, behaving in a destructive manner, and so on.

Concurrent implementation of N-version programming is often possible.

Recovery Blocks. In using recovery blocks, again a number of routines are written (in isolation) ideally using different approaches. In addition, an acceptance test is provided and the first routine to satisfy the acceptance test is selected. The structure of a recovery block typically takes the form of a number of alternative actions to be taken. Their format is captured in the following:

ENSURE	Acceptance test
BY	Primary module
ELSE_BY	First alternative
ELSE_BY	Second alternative ...
ELSE_BY	Nth alternative
ELSE_ERROR	Exception raised

The primary module is the preferred option. The sequence of events is as follows: on entry to the

recovery block, a recovery point P is established; on reaching this, record the state S of the system. The primary module runs and produces a result; if this is accepted by the acceptance test, then normal execution can continue, i.e., typically, the statement following the recovery block is executed; if the acceptance test fails, then recreate the recorded state S of the system at the recovery point P and invoke the next alternative. Continue until the result passes the acceptance test or there are no alternatives remaining. In the latter case, an exception is raised.

The complexity of acceptance tests has to be limited; otherwise they may introduce more faults into the system, e.g., violation of performance targets. The design of good acceptance tests is not a straightforward matter; most do not guarantee correct behavior and additional checks are needed if that is a requirement. Acceptance tests need to be simple, especially in real-time systems where there need to be guarantees of performance. On occasion, null alternatives can be used in recovery blocks to provide an effective fault tolerant strategy for real-time systems.

It is possible to have different strategies in relation to the alternatives within the recovery block. For instance, all alternatives are independent and of equal status; alternatively, prioritize the alternatives (e.g., for efficiency reasons), or finally have degraded alternatives.

In the use of recovery blocks, it is desirable that execution of a routine should not adjust the environment, since the effect of that execution may have to be discarded. Thus reestablishing the state S of the system must be simple.

Comparison of Mechanisms. A comparison can be offered between the N-version programming and recovery block concepts. In N-version programming, the voting check is a powerful mechanism for error detection but inexact voting causes complexity in the software and this can introduce new faults. In recovery blocks, acceptance tests are often difficult to devise and often do not provide a guarantee of correct execution. Generally, in both cases, the tendency exists for different version of components to access common data structures and this tends to compromise the independence of designs.

The principles behind software fault tolerance can be applied equally at the component level and at the systems level. When applied to individual components, redundancy is tailored to the specific

needs and structure of those components. At the component level, redundancy can be effective but can only deal with those faults specific to the component in question. At the systems level, redundancy is more expensive because of its generality but can consequently deal with a greater range of faults.

ANDREW D. MCGETTRICK

Soil Contamination Risk

Soil is generally defined as the unconsolidated mineral or organic material on the immediate surface of the earth that serves as a natural medium for the growth of land plants. Additional functions of soil should be fully recognized, such as harboring groundwater supplies, producing and recycling organic material, storing and recycling organic waste [1]. Soil is a “vital” medium hosting most of the biosphere and is essentially a nonrenewable natural resource owing to the very slow processes for its generation. Contamination is one of the major threats to soil conservation, others being erosion, sealing, organic matter decline, salinization, compaction, and landslides [2]. Soil-contaminating substances can be roughly divided into heavy metals, organic contaminants such as *persistent organic pollutant* (POPs) (see **Persistent Organic Pollutants**), and nutrients. Pollutants may enter the soil through direct application, as is the case with pesticides and fertilizers (included sludge amendments), accidents, spills, or improper uses of industrial waste (see **Hazardous Waste Site(s)**). Dry deposition of industrial air emissions or long-range transport of volatile substances can also result in soil contamination. Contamination may have an impact on most soil functions including the support to human living. Since soil is the interface between area, water, and rock compartments and the platform for human activities and landscape, the term *land contamination* is often preferred to that of soil contamination. The term *land* indicates the need for an integrated approach to contaminated soil, surface water nearby, and groundwater beneath. It also clearly refers to value placed on land and soil by humans: land is often a private property and soil is a part of the landscape.

Some key concepts in the management of contaminated soils are the following:

- Contaminated soil should be closely related to the management of air and water compartments (see **Air Pollution Risk; Water Pollution Risk**).
- The definition of sustainable solutions requires a proper consideration of the temporal and spatial dimensions.
- Long-term care objectives should be defined, taking into consideration the mobility and degradability of contaminants.

- A distinction is usually made between the historic contamination (inherited from the past) and the prevention of future contamination.
- With regard to the spatial dimension, the remediation of contaminated land is closely linked to spatial planning and is usually driven by the “fitness for use” concept.
- A distinction is usually made between local and diffuse contamination, the former being a problem to be solved by the landowners, and the latter being a problem related to multiple stakeholders and environmental protection strategies on a larger scale.

In the following sections the fundamentals of both human health and ecological risk assessment for soil contamination will be introduced. The application of risk assessment in the derivation of soil quality standard (SQS) and site-specific assessment will be described thereafter.

Human Health Risk Assessment

The human health risk assessment of contaminated soils implies the analysis of the likelihood and magnitude of adverse effects on human health arising from the direct or indirect exposure to toxic substances in soil.

The potential exposure pathways of human beings to soil contaminants include e.g., direct contact, inhalation, ingestion of particles, and drinking of contaminated groundwater. Which are the most relevant exposure pathways mainly depend on the physico-chemical properties of the contaminants.

The ingestion of contaminated soil is one of the main exposure pathways for immobile contaminants (those strongly adsorbed onto soil particles). Several studies proved that children can ingest significant amount of soil per day: e.g., the Exposure Factor source book published by the United States Environmental Protection Agency (USEPA) [3] reports measured amounts of ingested soil ranging from *ca.* 100 to 1400 mg kg⁻¹ day⁻¹ (lower and upper percentiles figures) with means of 383 (soil ingestion only) and 587 mg day⁻¹ (soil and dust ingestion).

For volatile contaminants, rather than evaporation in open air, the accumulation in enclosed spaces (through cracks in walls and pavements) appears to be the major exposure pathways.

The ingestion of contaminated groundwater appears to be the most relevant exposure pathway for relatively soluble compounds. Relatively soluble contaminants can leach through the unsaturated soil layer to the groundwater body below. If the aquifer is exploited for domestic uses, contaminants are ingested by drinking uses or inhaled during shower.

Diet exposure is by far the most relevant exposure pathway for bioaccumulating substances. Contaminants can be taken in by vegetables. They accumulate in roots, plants, and fruits and, consequently, in meat and dairy products.

In some cases, the contact between contaminated groundwater and surface water can lead to bioaccumulation in fishes.

Potential adverse effects on human health include irritation, sensitization, acute or chronic systemic toxicity, mutagenic and carcinogenic effects, and fertility and developmental effects, depending on the toxicological properties of the contaminants. A further insight on the assessment of human health risk *via* environmental exposure to hazardous substances in soil or waste matrices can be gained in the encyclopedia entry **Hazardous Waste Site(s)**.

Ecological Risk Assessment

Ecological risk assessment (*see* **Ecological Risk Assessment**) – applied to soil contaminants – concerns the following adverse effects [4]:

- effects on soil functions, and particularly on the capacity of soil to act as a substrate for plants and those organisms important for proper soil functioning and nutrient cycle conservation;
- effects on plant biomass production;
- effects on soil, above-ground, and foliar invertebrates, which are the basis of the terrestrial food web and cover essential roles as pollinators, detritivores, saprophages etc.;
- effects on terrestrial vertebrates;
- accumulation of toxic compounds in food items and through the food chain (as it is also considered in relation to human health).

Typical terrestrial receptors include soil microbes, invertebrates (e.g., beetles) including soil-dwelling invertebrates (e.g., insect larvae, worms, nematodes), plants, amphibians, reptiles, birds, and mammals. The exposure to soil contaminants includes direct

contact routes, like passive diffusion or active uptake, for plants and soft-bodied soil-dwelling organisms; incidental ingestion of soil particles for hard-bodied terrestrial invertebrates (e.g., beetles, centipedes) and, above-soil wildlife (e.g., small mammals and birds). Inhalation of highly volatile substances can be a significant exposure pathway for wildlife in the case of accumulation in enclosed spaces (e.g., lairs). In general, above-soil wildlife is mainly exposed to pollutants bioaccumulated through the food web (secondary poisoning) [5].

Ecological risk assessment of soil contaminants deals with many sources of uncertainty. First of all, it is very difficult to extrapolate effects to the ecosystem from the effects evidenced on a single species. Being true for the aquatic ecosystem, this concern is even more relevant for the terrestrial ecosystem owing to its overwhelming complexity. The risk assessment usually relies on results from laboratory tests with species representative of that environmental compartment. The extrapolation from monospecies tests to multispecies ecosystem is usually obtained by application of assessment factors, which is a very rough and conservative approach. How effects on a single species are reflected on populations, communities and the ecosystem is poorly known. Phenomena such as adaptation and pollution-induced community tolerance have been demonstrated in soil microbial communities. In this context, mesocosm studies can provide interesting results, but they are time consuming, costly, and not easily applicable to regulatory risk assessment.

The second source of uncertainty is associated with the poor understanding and modeling of environmental availability and bioavailability of soil contaminants. Exposure assessment to toxic chemicals in soil requires information on the concentration that is available to the organism in soil, which may be only one fraction of the total concentration, i.e., the bioavailable fraction. *Bioavailability* can be defined as the dynamic process that comprises the physicochemical desorption and the physiological driven uptake of the contaminant by the terrestrial organism. Soil pollutants can be sequestered by adsorption onto mineral surfaces and organic matter, diffusion in microporous media, and encapsulation. For organic pollutants, adsorption (and absorption) is usually related to the organic matter content, while for *heavy metals* parameters like pH, clay content, and

cation exchange capacity play a major role. Moreover, the bioavailability of metals depends on the chemical speciation of the dissolved fraction, which in turn depends on complex geochemical equilibriums. Refined methods for the estimation and incorporation of bioavailability in the risk assessment process are needed [6–8]. Related to the bioavailability concept is the need to normalize ecotoxicological data according to the type of soil used in the test. For comparison purposes the results from various tests should be recalculated for standard soil characteristics (e.g., 10% organic matter and 25% of clay).

The third relevant source of uncertainty is the poor availability of ecotoxicological data about terrestrial organisms as compared to aquatic organisms. This is usually overcome by applying equilibrium partitioning methods to aquatic organism ecotoxicological data. This method relies on two pragmatic (but weak) assumptions: that bioavailability, bioaccumulation, and toxicity are closely related to pore water concentrations and that sensitivities of aquatic organisms and terrestrial organisms are comparable. The poor availability of data significantly limits the possibility of applying probabilistic effect assessments, like the derivation of species sensitivity distributions (statistical distribution describing the variation in toxicity of a certain compound or mixture among a set of species) [9].

The fourth source of uncertainty is the oversimplification of the compartmental approach. The distinction between soil and above-ground compartments does not properly address the complexity of the terrestrial ecosystem [10].

Derivation of Soil Quality Standards (SQS)

Environmental quality standards for soil contamination have been issued in several countries and are usually based on quantitative risk assessment methodologies.

For the derivation of SQS, the risk assessment is applied to standard scenarios, including exposure pathways of concern, types of human and ecological receptors, and toxicological endpoints. In practice, the definition of standard scenarios incorporates relevant decisions about what to protect and to which extent. For example, in some cases only human health is considered and potential effects to ecological receptors are not. The contamination of groundwater is

not always included, but addressed separately. As for ecological receptors, whether to include microbial communities (biogeochemical cycles), soil organisms and plants, terrestrial wildlife, or aquatic organisms in (hypothetically affected) surface water bodies is a matter of choice. For human health risk assessment, potentially highly exposed subpopulations are not always considered: e.g., people consuming vegetables grown on contaminated soils or children with pica behavior (voluntary ingestion of significant amount of soil). Besides the definition of conceptual exposure models, conservativeness of exposure input values may also vary according to the concern for that specific exposure pathway. For toxicological and ecotoxicological assessment, the definition of endpoints of concern is usually inspired by the greatest conservativeness. Variability can be found on setting assessment factors and protection levels in the derivation of predicted no-adverse-effect concentrations. For example, when species sensitivity distributions are applied in ecological risk assessment, acceptable concentrations can be set to protect a certain percentage of species, usually ranging from 50 to 95% according to the objective of the SQS application. The rationale behind different choices in SQS derivation methods can be related to scientific arguments, but more often it depends on geographical, sociocultural, and political factors. It should be recognized, therefore, that SQS derivation methods are the product of sound science and conventional assumptions depending on risk societal valuing. Differences among procedures adopted by various national and international authorities may lead to wide variations (up to four orders of magnitude) of SQS values for the same contaminant, while the identification and distinction of reasons behind differences can be extremely difficult [11].

Site-Specific Risk Assessment

Site-specific risk assessment aims at estimating the risk for human health or ecological receptors at a specific site. Differing from SQS derivation methods, site-specific assessment takes into account local conditions that affect exposure or effects.

It should be borne in mind that soil contamination may concern small spots as well as very large areas or regions, according to the type of polluting source and contaminant mobility. The larger the contaminated area, the more important it is to characterize

the spatial distribution of the contaminant. Owing to spatial heterogeneity and the often accidental nature of contamination, concentrations of pollutants may vary remarkably over very short distances. Moreover, it is common and often unavoidable to have relatively small data sets derived from limited sampling in both the horizontal and vertical dimensions. Among different data interpolation methods to estimate the concentration distribution over the site, geostatistical methods like kriging [12] have the merit of being based on the proved spatial correlation of the observed concentrations and providing an indication of the uncertainty of the estimate [13, 14].

Solvency

Solvency is the ability of an insurance company to pay future claims as they fall due. This involves that the insurer must have sufficient assets not only to meet the liabilities but also to satisfy statutory financial requirements.

It is important for the supervisor to not only ensure the protection of the policyholders but also ensure the stability of the financial market.

The available solvency margin (ASM) is the difference between assets (A) and liabilities (L), i.e.,

$$ASM = A - L \quad (1a)$$

This definition, in terms of a solvency margin, was first given in [1]. It is necessary to distinguish between this actual margin and one required by the regulator. The theoretical requirement can in some jurisdictions be a minimum amount, and in others just a target or an early warning signal. If the insurer has an ASM above the required level, it can continue to be a going concern. Otherwise it has to be a dialogue between the insurer and the supervisor on what steps to take to get the ASM above this level. Some systems, e.g., the National Association of Insurance Commissioners' (NAIC) risk-based system in the United States, have an intervention ladder between the upper target and the absolute minimum level.

We assume a jurisdiction with two regulatory capital requirements;^a the target will be called *the solvency capital requirement* (SCR) and the absolute minimum will be called *the minimum capital requirement* (MCR). Ideally we have

$$MCR < SCR \leq ASM \quad (2)$$

Two concepts of solvency could be defined: (a) the position when liabilities could be paid at a breakup or at a runoff of the company or when it could be transferred to a willing partner and (b) the position when the company can pay all its debts as they mature (the going concern approach).

The first position may be obtained when $ASM \leq MCR$ and the second when $ASM \geq SCR$. This is also discussed in [2, 3].

One way of describing the strength of solvency is to evaluate the *ruin probability* (see **Ruin Theory**), i.e., the probability that the insurer having an initial $ASM \geq SCR$ will become insolvent during a

chosen time horizon $(0, T)$, see [4]. In the legal meaning insolvent means the break of the MCR, i.e., $ASM \leq MCR$. T is usually chosen according to the accounting period, i.e., at least a 1-year period.

In the literature there are a number of different formulas for the assessment of the capital requirement, especially for the MCR. In the beginning of the 1990s, a tendency was to seek rules that take into account all risks that an insurance company is facing. Systems of this kind are usually called *risk-based* and hence a risk-based capital requirement. A thorough discussion of the insurers' risks is given in [5, 6].

Historical Treatment of Solvency

The pioneering works done by Cornelis Campagne in the Netherlands at the end of the 1940s and by Teivo Pentikäinen in Finland in the beginning of the 1950s are important, as they introduced the solvency research for insurance undertakings, see e.g. [1, 2, 7]. The works done by Campagne became the framework for the solvency directives within the European Union (EU). The first EU directives framed in the 1970s have been amended twice during the 1980s and 1990s. On the basis of the discussion in reference [8], the EU Parliament adopted revised directives in 2002, Solvency I, and at the same time initiated a future risk-based system. This new system will be implemented within Europe around 2012. The basic ideas of Solvency II are given in [9].

As many countries in Europe had got the insurance directives during the 1970s implicating minimum solvency margins, research on solvency assessment was initiated. Work was done not only in, e.g., United Kingdom [10–13] and the Netherlands [3, 14] but also in Finland [15–17] and Norway [18–20]. The best reference and summary of different solvency assessment methods used in the middle of the 1980s are given in [3].

The research and works done were all stepwise toward a risk-based capital (RBC) approach. The NAIC introduced RBC systems in 1992 and 1993. At the same time the Canadian Office of the Superintendent of Financial Institutions (OSFI) introduced a risk-based system for life insurers. Risk-based systems were also introduced in Australia, Singapore, and Japan. While waiting for a new European system, different approaches were discussed or introduced in

United Kingdom, Switzerland, the Netherlands, Denmark, and Sweden, see e.g. [6].

Historically, there have been problems in comparing the available and required solvency margins between companies (and especially between companies in different countries). Assets have either been defined as book values or market values. The main problem, though, has been the technical provisions^b as these have included implicit margins to protect policyholders. These margins have been set by the actuaries and have reflected the prudence of the company. In the EU the incomparability of the provisions has been recognized and discussed.

Risk-Based Systems

The International Actuarial Association (IAA) and the International Association of Insurance Supervisors (IAIS) have issued standards and guidance regarding the assessment of insurer solvency.^c The main aim is to set up standards that make it possible to compare the valuation of the reserves, the capital requirement, etc., in different jurisdictions.

The total balance sheet approach was introduced by IAA (see [5]). It should not only recognize the asset and liability sides of the balance sheet, but also the interdependence between them and the impact of the SCR, MCR, and the eligibility of capital covering the requirements. The technical provisions are the reserves set aside to cover the liabilities the company face according to the insurance contracts.

In the banking supervisory system, *Basel II* (see **From Basel II to Solvency II – Risk Management in the Insurance Sector**), a three-pillar approach was introduced. A similar approach will be adopted within the EU Solvency II system. It consists of

- Pillar I: The quantitative requirements
- Pillar II: The qualitative requirements
- Pillar III: Statutory and market reporting.

The first pillar includes the calculation of the SCR according to a standard model (e.g., factor based), or the introduction of partial or full internal models. It also includes rules on provisioning and eligible capital. The second pillar focuses on the supervisors and their review process, e.g., a company's internal control and risk management, the approval of using partial or full internal models in Pillar I and its validation. The supervisor can also impose a company

to increase its SCR (capital add-ons) if it believes that the capital is not adequate or that the management is not sufficient. The third pillar includes the reporting to both the supervisor and the market promoting the market discipline and greater transparency, including harmonization of accounting rules.

A total balance sheet approach is based on common valuation methodologies. It should make optimal use of information provided by the financial markets [9] in getting market values when they exist ("mark-to-market") or getting market consistent values when they do not exist ("mark-to-model"). This is called *the economic value*. In a traditional actuarial valuation of present value a deterministic interest rate function is normally used, but in a market consistent valuation the deterministic interest rate is changed for a stochastic function, a deflator, reflecting the market price. The valuation should be prospective and all cash flows related to assets and liabilities should be discounted and valued at current estimate (CE). This valuation should use a relevant risk-free yield curve and be based on current, credible information and realistic assumptions. A risk margin covering the uncertainty linked to future cash flows over their whole time horizon can be added to the CE. An alternative in using a deflator function in market consistent valuation is to use a replicating portfolio in valuing the liabilities, i.e., a portfolio of assets that replicates the cash flow of liabilities most closely. One such technique is to use a valuation portfolio (VaPo), see [25–28].

A risk-adjusted CE of the liabilities is called *economical* technical provisions or market value of liabilities (MVL). The corresponding risk-adjusted assets is called *market value of assets* (MVA). The risk margins should be determined in a way that enables the insurance obligations to be transferred to a third party or to be put in runoff, cf. e.g. [9].

In the valuation procedure, hedgeable assets and liabilities should be valued by a mark-to-market approach, as any risk margins are implicit in observed market prices. Nonhedgeable assets and liabilities should be valued by a mark-to-model approach, i.e., a CE requires the calculation of an explicit risk margin. This is illustrated in Figure 1.

In terms of a total balance sheet approach, Equation (1a) is written as

$$ASM = MVA - MVL \quad (1b)$$

Figure 1 Current estimates of assets and liabilities are calculated, namely, CEA and CEL, respectively. An asset risk margin, ARM, is then deducted from the CEA to get the market values of assets, MVA. A liability risk margin, LRM, is then added to the CEL to get the market value of liabilities, MVL

The asset risk margin (ARM) is a risk margin deducted from the CE of assets owing to uncertainty in models and parameters. Valuations of derivative instruments may include uncertainty in the models used, see e.g. [21], giving rise to an uncertainty in the valuation.

As there is no liquid market for insurance risks, we need to use a mark-to-model approach to determine the MVL, i.e., to model a risk margin on top of the current estimate of liabilities (CEL). This liability risk margin (LRM) should take account of the uncertainty of models and parameters, and be such that the insurance contracts could be sold to a “willing buyer” or put in runoff. In economic terms the risk margin is often called a *market value margin* (MVM).

In Australia, the risk margin for nonlife insurance is calculated as the 75th percentile of the distribution function where the unbiased mean equals CEL. Using an economic approach, a proxy of the LRM (or MVM) can be given by a cost-of-capital (CoC) approach. “The CoC approach bases the risk margin on the theoretical cost to a third party to supply capital to the company in order to protect against risks to which it could be exposed” [22, 23]. The CoC approach was first introduced in the solvency context in the Swiss solvency test, see [6, 24].

The MVL and the capital requirement, in terms of SCR, have somewhat different roles in a solvency regime. The LRM is a safeguard to the CEL.

The SCR provides further safeguard to the policyholders by protecting both the MVL and the MVA and their interaction. The SCR should be calibrated such that it could withstand current year claims’ experience in excess of CE and that assets still exceed the MVL at the end of a defined time horizon, with a certain degree of confidence, say 99.5%, or that the available capital (ASM) could withstand a range of predefined shocks or stress scenarios over the defined time horizon.

Let $X = MVL$ and Y be two stochastic variables, where Y is the assets covering the MVL, see Figure 2. The SCR is now defined as a function of $Z = h(X, Y)$. We can assume an unknown and probably skewed distribution function of Z with $\mu_Z = MVL$. The SCR is now defined as a stochastic variable: $SCR = f(Z) - \mu_Z$, where $f(Z)$ is usually measured by the *value at risk* (VaR) (see **Value at Risk (VaR) and Risk Measures**) or *TailVaR*^d risk metrics. The capital requirement (SCR) is thus the difference between the upper quantile (if using VaR) in the skew distribution and the mean (“assets covering the MVL”), see Figure 2. The function $h(X, Y)$ includes both the risks inherent in the liabilities (X) and the assets covering them (Y) as well as the interaction between the assets and liabilities.

To model the SCR, the IAA [5] has proposed five main *risk categories*, mainly based on the Basel II accord and insurance characteristics: (a) insurance

Figure 2 The SCR is calculated as the difference between a function of $h(X, Y)$ and the mean of the distribution. The distribution is a function of the $X = MVL$ and the corresponding assets covering the liabilities (Y)

risk (or underwriting risk), (b) credit risk, (c) market risk, (d) operational risk, and (e) liquidity risk. If a risk category is not possible to model, it should be treated as a Pillar II assessment, i.e., under the supervisory review process. The five risks are used both for solo entities and for insurance groups or financial conglomerates. There is also a sixth main risk category that can be introduced for groups or conglomerates: the group or participating risk. Examples of the latter type are an internal reinsurance program within an insurance group or the possibility that a bank is insuring its credit risks to an insurance company in the conglomerate.

The modeling is made in a top-down fashion. Each of the main risk categories is in the next step of modeling split up into subrisks, which in turn could be split up into sub-sub risks, etc. On the contrary, the calculation of the capital requirement is made in a bottom-up approach, see [29], starting from the lowest level.

To model the SCR we use a pragmatic solution. We use the notation of the standard deviation principle as the base-line approach [5] and apply the VaR and the TailVaR as risk metrics. The VaR approach is illustrated in Figure 2. We have two main problems to deal with: the nonnormality and the nonlinearity.

With four main risk categories the SCR could be written as

$$C = \sqrt{\begin{aligned} &C_1^2 + C_2^2 + C_3^2 + C_4^2 + 2\rho_{12}C_1C_2 \\ &+ 2\rho_{13}C_1C_3 + 2\rho_{14}C_1C_4 + 2\rho_{23}C_2C_3 \\ &+ 2\rho_{24}C_2C_4 + 2\rho_{34}C_3C_4 \end{aligned}} \quad (3)$$

where $C_i = k\sigma_i$, and k is a quantile function that is clearly defined for a standard normal distribution.

Nonnormality

Using a first-order “normal power (NP) approximation” provides us a solution to the nonnormality problem. VaR (quantile) and TailVaR (expected shortfall)^c of a skew standard distribution $F(\cdot)$ can be expressed in terms of the VaR (quantile) and TailVaR of a standard normal distribution $\Phi(\cdot)$. For the VaR case see [6, 30, 31] and for the TailVaR case see [32, 33].

To be more pragmatic, even if we have started with $C_* = k(\gamma_1)\sigma_*$, we may choose to let C_* be the result of scenarios or stress tests (i.e., the capital charge based on stress tests).

Nonlinearity

In assessing diversification effects, IAA [5] has proposed the use of *Copulas* (see **Copulas and Other Measures of Dependency**) as they can recognize

dependencies in the tail of the distributions. Extreme events (*see* **Extreme Value Theory in Finance**) and tail dependencies are important for the insurance industry. In reference [29] it is proposed, as a pragmatic solution, to adjust the correlation matrix with tail correlations instead of using the more complex copulas approach.

Accounting

In order not to burden the insurance undertaking with both a statutory requirement and an accounting requirement, it would be desirable to have one reporting system that could be used by both purposes. The International Accounting Standard Board (IASB) has been working toward a consistent approach to insurance accounting. The work done by IASB has been in coordination with the United States Financial Accounting Standard Board (FASB).^f A presentation of IASB's work is given in reference [34].

End Notes

- ^a. If we only have one level of requirement, then $SCR = MCR$.
- ^b. As an example: Within EU the solvency requirement for life insurance is mainly 4% of the technical provisions. However, as these are calculated with prudent assumptions, e.g., in mortality, the more prudent a company is, the higher its requirement is!
- ^c. See further reading.
- ^d. The TailVaR is a coherent risk metric.
- ^e. We assume that the distributions are continuous.
- ^f. For more information see its website: www.fasb.org.

Spatial Risk Assessment

Spatial risk assessment concerns the analysis of a risk outcome within a geographically bounded region (such as a country, county, or census tract). The risk could be defined to be health risk or risk of adverse events, such as accidental occurrences or toxic spillages (see **What are Hazardous Materials?**). In general, *risk* can be broadly defined to mean the chance of a particular outcome (the probability of loss or threat). Loss or threat could be to health of people or ecological systems, either by a health insult or, for example, criminal activity. Alternatively, loss could be financial in terms of fraud or monetary loss. In engineering applications, loss or threat may be related to failure of components. Many of the techniques that will be mentioned here have general applicability across these different risk scenarios. However, for simplicity, the focus is on health risk and situations where an adverse health outcome is to be detected in space. A general reference in the area of risk assessment is [1].

Detection of Elevated Risk Areas

Georeferenced (or *spatial*) data can be analyzed for evidence of adverse outcomes. Maps of disease incidence for example (i.e., the spatial distribution of case addresses of disease) can display peaks of risk and these can be analyzed with respect to “significant” excesses of risk. The assessment of the degree of significance is a statistical issue. A range of methods are available for the assessment of such localized areas of risk. Often these areas are called *clusters*, and *cluster detection* is a major activity within public health, crime, and financial surveillance. Clusters can suggest localized environmental risk elevation or, in the case of crime statistics, some elevated crime risk. Spatial clustering can be detected *via testing* or *via modeling*. There has been large literature in the area of cluster testing, and software is readily available as special packages or functions (e.g., SatScan <http://www.srab.cancer.gov/satscan/>, ClusterSeer <http://www.terraser.com/products/clusterseer.html> or DCluster in R <http://cran.r-project.org/>). Modeling of risk is less well developed but has seen some recent advances using Bayesian

hierarchical modeling (see e.g. Lawson and Denison [2]) (see **Bayesian Statistics in Quantitative Risk Assessment**).

Risk Detection

The basis of the detection of areas of elevated risk is a criterion for labeling areas as “in excess”. Definition of what constitutes an area of excess and also what constitutes significance of the area is important. One definition of excess leads to what is known as “*hot spot*” clustering. This is where any area, regardless of shape or size, is declared to be a cluster if the risk estimate in the area is “significantly” high. Often this is a natural definition in that we are often interested in finding any unusual elevated risk. However, sometimes the risk excess can have a particular form and it is only when this form is found that a significance can be assessed. For example, it might be that the shape of the cluster or spatial integrity is important. A cluster of relatively regular conical or circular shape might suggest a central source for the risk. In the case of putative source risk assessment (see e.g. Elliott *et al.* [3, Chapter 9]), the aim is to detect any evidence for an association between the adverse health outcomes and a fixed known location (believed to be the source of risk). This putative source could be the location of an incinerator or nuclear plant or waste dump site. An early example was John Snow’s analysis of cholera deaths in relation to the Broad Street pump in London [4]. More recent examples include the Armadale (UK) lung cancer epidemic, and the Sellafield nuclear reprocessing plant (UK) and the risk of childhood leukemia (see e.g., Lloyd [5]; Kinlen [6]) (see **Radioactive Chemicals/Radioactive Compounds**). Around fixed locations, it is feasible to set up statistical models for the analysis where the outcome variables are (disease) incident counts (or at a finer level, event locations themselves) and the explanatory variables are exposure surrogates such as distance and direction around the fixed location. In this case, the focus is usually on evidence for a decline with distance from the source or concentration around a directional axis. This often implies that some form of circular clustering is assumed. Such models are simple to fit using standard software such as R or SAS.

When the location of clusters or areas of elevated risk are unknown, the problem is more difficult to

analyze statistically. If one adopts a method that can assess whether the localized risk is elevated, then that method can be used for *hot spot* detection with small areas. If on the other hand the clusters are thought to be larger than just one area, methods that use neighborhoods might need to be employed. Neighborhood methods assume that contiguity is important in clustering.

Definition of Clusters and Clustering

Two extreme forms of clustering can be defined. These two extremes represent the spectrum of modeling from nonparametric to parametric forms and there are appropriate statistical models and estimation procedures associated with these forms. First, as many researchers may not wish to specify *a priori* the exact form/extent of clusters to be studied, a nonparametric definition is often the basis adopted. Without any assumptions about shape or form of the cluster, the most basic definition would be as follows: *any area within the study region of significantly elevated risk* [7, p. 112].

This definition is often referred to as *hot spot clustering*. In essence, any area of elevated risk, regardless of shape or extent, could qualify as a cluster, provided the area meets some statistical criteria. Note that it is not usual to regard areas of significantly low risk to be of interest, although these may have some importance in further studies of the etiology of a particular disease.

Second, at the other extreme, we can define a parametric cluster form: *the study region displays a prespecified cluster structure*.

This definition describes a parameterized cluster form that would be thought to apply across the study region. Usually, this implies some stronger restriction on the cluster form and also on some region-wide parameters that control the shape and size of clusters. For example, infectious diseases may display particular forms of clustering depending on the spread rate and direction.

Nonspecific Clustering

Nonspecific clustering is the analysis of the overall clustering tendency in a study region. This is also known as *general clustering*. As such, the assessment of general clustering is closely akin to the assessment

of spatial autocorrelation. Hence, any model or test relating to general clustering will assess some overall/global aspect of the clustering tendency of the disease of interest. This could be summarized by a model parameter (e.g., an autocorrelation parameter in an appropriate model) or by a test that assesses the aggregation of cases of disease. For example, a model often assumed for disease relative risk estimation (the Besag, York, and Mollié (BYM) model) uses a correlated prior distribution that has a parameter that describes the clustering behavior. It should be noted at this point that the general clustering methods discussed above can be regarded as *nonspecific* in that they do not seek to estimate the spatial locations of clusters but simply to assess whether clustering is apparent in the study region. Any method that seeks to assess the locational structure of clusters is defined to be *specific*.

An alternative nonspecific effect has also been proposed in models for tract-count or case-event data. This effect is conventionally known as *uncorrelated heterogeneity* (or overdispersion/extra-Poisson variation in the Poisson likelihood case).

Specific Clustering

Specific clustering involves the analysis of the locations of clusters. Location could be very important in the assessment of risk localization. This approach seeks to estimate the location, size, and shape of clusters within a study region. For example, it is straightforward to formulate a nonspecific Bayesian model for case events or tract counts that includes heterogeneity. However, specific models or testing procedures are less often reported. Nevertheless, it is possible to formulate specific clustering models for the case-event and tract-count situation.

Focused versus Nonfocused Clustering

Another definition of clustering seeks to classify the methods based on whether the location or locations of clusters are known or not. Focused clustering is *specific* and usually seeks to analyze the clustering tendency of a disease or diseases around a known location. Often this location could be a *putative pollution source* or health hazard (as discussed above). Nonfocused clustering does not assume knowledge of a location of a cluster but seeks to assess either

the locations of clustering within a map or the overall clustering tendency. Hence, nonfocused clustering could be specific or nonspecific.

Hypothesis Tests for Clustering and Cluster Modeling

The literature of spatial risk assessment of health data has developed considerably in the area of hypothesis testing and, more specifically, in the sphere of hypothesis testing for clusters. Very early developments in this area arose from the application of statistical tests to spatiotemporal clustering. Spatiotemporal clusters are short duration bursts of excess risk, which are spatially compact, and are a particularly strong indicator of the importance of a spatial clustering phenomenon. As noted above, distinction should be made between tests for general (nonspecific) clustering, which assess the overall clustering pattern of the disease, and the *specific* clustering tests where cluster locations are estimated.

For case events (where the residential address location of cases is known), a few tests have been developed for nonspecific clustering. Specific nonfocused cluster tests address the issue of the location of putative clusters. These tests produce results in the form of locational probabilities or significances associated with specific groups of tract counts or cases. Openshaw and coworkers [8] first developed a general method that allowed the assessment of the location of clusters of cases within large disease maps. The method was based on repeated testing of counts within circular regions of different sizes. An alternative statistic has been proposed by Kulldorff and Nagarwalla [9] (the scan statistic). The test can be applied to both case events and tract counts.

Focused tests have also been developed and there is now a range of possible testing procedures (see e.g. Lawson [7, Chapter 7]).

Cluster modeling has seen some development but has not developed as fully as testing procedures. Usually the successful models are Bayesian with prior distributions describing the risk aggregation behavior (see e.g. Lawson and Denison [2]).

Spatiotemporal Risk Analysis

Spatiotemporal risk analysis focuses on the study of the geographical pattern of risk and its variation over time. The *spatial analysis* of risk usually consists of a static examination of a surface to assess where unusual risk patterns occur. Inevitably, with almost all risk subjects, whether health- or crime- or finance-related, patterns of risk vary with time and often it is this time variation (or *temporal* variation) that is of interest. Unusual risk patterns could take a variety of forms when expressed as features on a spatial surface. Often clusters of risk are the focus, and these could be circular, oblong, linear, or have a relatively indeterminate pattern. In addition, in *spatiotemporal analysis* of risk, we are interested in temporal effects and so we might want to assess how *change* occurs in the spatial risk surface. The detection of changes in risk and, in this case, risk surfaces is a major focus area for *surveillance*. Disease surveillance, for example, when applied to spatial data, focuses on the ability to detect changes in disease risk over space and time (see Farrington and Andrews [1] and Lawson [2]). There are a range of approaches available to this end, depending on what type of unusual risk pattern or aberration is focused on.

Aberration types

1. Temporal

In temporal surveillance, a time series of events is available (usually either as counts of disease in intervals or as a point process of reporting or notification times). With time series of discrete counts, the aberrations that might be of interest (suggesting “important” disease changes) are highlighted in Figure 1. In this figure, there are three main changes (A, B, C). The first aberration (A) is a sharp rise in risk (jump) or a change point in level. The second aberration (B) that might be of interest is a cluster of risk (an increase and then a decrease in risk). However, this can only be detected retrospectively. The third aberration (C) is an overall process change where not only the level of the process is changed but also the variability is increased or decreased.

When a point process of event times is observed, then action may need to be taken whenever a new event arrives. Aberrations that are found in point processes can take the form of unusual aggregations of points (temporal clusters), sharp changes in rate of occurrence (jumps), and overall process change (as above).

2. Spatiotemporal

If a spatial domain (map of events) is to be monitored, then spatial and spatiotemporal aberrations must be considered. Spatial aberrations could consist of discontinuities in risk between regions (jumps in risk across region boundaries), spatial clusters of risk (localized aggregations of cases of disease), and long-range trend in risk.

When maps are monitored in time, then *changes* in the above features might be of interest. In the infectious disease case, for example, the development of new clusters of infectious disease in time might signal localized outbreaks.

Multivariate Issues

In surveillance systems designed for prospective surveillance, whether for finance or health or other foci, many of the above features would have to be detectable across a wide range of data streams. Not only would whole data streams be monitored, but subsets of data streams may be required to be examined. For example, for early detection of effects, it may be important to monitor “high-risk” subsets (such as old or young age-groups for health data). Also correlations between subsets may be important

Figure 1 Schematic features of changes/aberrations found in temporal surveillance (Log R risk: log relative risk)

Figure 2 Battlefords, Saskatchewan: epidemic curve and time series of over-the-counter (OTC) pharmaceutical sales from January to May 2001 [Reproduced from Edge *et al.*, *Canadian Journal of Public Health* **95**, 2004. © Canadian Public Health Association.]

for making detection decisions. In addition, if maps are to be monitored over time as well as time series, then the problem intensifies considerably. The *Biosense* system developed by centers for disease control (CDC) (<http://www.cdc.gov/phn/component-initiatives/biosense/index.html>) has a multivariate and mixed stream (spatial and temporal) capacity.

Data Collection

Data for space–time risk analysis are often difficult to gather. For health systems, this would mean obtaining historical records to allow estimation of “normal” background risk evolution and also a spatial resolution fine enough to allow monitoring of risk spatially. For health data, very fine spatial resolution is often not available owing to confidentiality. For

crime or financial analysis, this fine scale may not be useful. In addition, early detection of events (such as bioterrorism infections or credit card fraud events) would be useful. Hence ancillary variables may need to be collected and monitored for this purpose. In public health analysis this is known as *syndromic surveillance* [3]. Figure 2 provides an example of some syndromic data where over-the-counter pharmaceutical sales are used to make early detection of gastrointestinal disease outbreaks.

Models

One of the current concerns about large-scale surveillance systems is the ability to correctly model the variation in data and to properly calibrate sensitivity and specificity with such a

multivariate and multifocus task. The application of Bayesian hierarchical modeling has been advocated for surveillance purposes and this may prove to be useful in its ability to deal with large-scale systems evolving in time in a natural way. For example, recursive Bayesian learning could be important. Clearly, computational issues could be paramount here given the potentially multivariate nature of the problem and the need to optimize computation time. Sequential Monte Carlo methods have been proposed to deal with computational speedups [4–6].

ANDREW B. LAWSON

Stakeholder Participation in Risk Management Decision Making

Stakeholder participation in risk-management decision making has had a checkered history. The nature of this has been perhaps best captured by MacKean and Thurston [1] who likened stakeholder participation to “eating spinach”. While people know that spinach is good for them in theory, they do not necessarily want to eat it themselves or even see it served at their dinner table. As a result of this attitude, there continues to be a gap between the concept and reality of stakeholder participation [2].

Nonetheless, the value of stakeholder participation in risk decision making is becoming increasingly recognized. This paper explores the benefits and challenges of stakeholder involvement, some of the factors contributing to successful stakeholder participation in the risk-management process, and the evaluation of stakeholder participation processes.

For the purposes of this discussion, “stakeholder” is being defined in terms of the broader concept of “interested and affected parties” coined by the US National Research Council [3]. “Affected parties” are “people, groups, or organizations that may experience benefit or harm as a result of a hazard, or of the process leading to risk characterization, or of a decision about risk. They need not be aware of the possible harm to be considered affected” [3, p. 214]. “Interested parties” are “people, groups, or organizations that decide to become informed about and involved in a risk characterization or decision-making process. Interested parties also may or may not be affected parties” [3, p. 215]. “Interested and affected parties” include risk practitioners, risk researchers, decision and policy makers, and the various “public”. They may be representatives of government, academia, industry, nongovernmental organizations, advocacy groups, and the general public, among others. However, the primary focus of many efforts in stakeholder participation has been on the specific needs of the “public”, and how, when, and why they should be involved in risk decision-making processes (*see Scientific Uncertainty in Social Debates Around Risk*).

Benefits and Challenges

Over the past 30 years of formalized risk decision making, the value of stakeholder participation has become increasingly evident. Involving stakeholders produces decisions that are responsive to varying interests and values, including those of the community. Stakeholder participation has also helped to prevent or resolve conflicts, build trust between various parties, and inform all parties about different aspects of the risk [4]. A review of 239 published case studies of stakeholder involvement in environmental decision making conducted by Beierle [5] showed that intensive stakeholder processes were more likely to result in higher quality decisions.

However, many risk professionals and decision makers are not yet “sold” on the value and feasibility of stakeholder participation. Some of the concerns frequently raised by agencies dealing with risk are that stakeholder participation will encourage the mobilization of antagonistic interests, will be too costly (in terms of both time and money), will be taken over by special interests, will undermine their authority, will be lacking in technical knowledge, and will be over dramatized [6]. There is also concern that trying to seek a compromise between a “squeaky wheel” and a more “moderate” stakeholder using traditional public participation may increase the likelihood of more extreme decisions [7].

Still others contend that stakeholder participation (particularly public participation) and scientific rigor are mutually exclusive processes [8]. Yet it must be remembered that different perspectives cannot change scientific facts or the laws of nature. What they can do is change how this information is interpreted and used in decision-making processes, thereby validating decisions about these risks [2]. Yosie and Herbst [9] suggested that stakeholder participation might actually function as a “social peer review” process that complements the scientific peer review process. In studies on risk assessment approaches for genetically modified foods, it was demonstrated that “more inclusive styles of decision making are not only more democratic but also more scientifically robust” [10, p. 129], on the basis that a strictly “scientific” approach will inevitably lead to an overly narrow focus of enquiry and policy judgment. Juanillo [11] also concluded that truly participatory communication on the risks and benefits of agricultural biotechnology leads to better regulatory policies.

However, many risk-management processes continue to be dominated by those conducting technical risk assessments, and provide only limited opportunities for interested parties to participate fairly and competently in the decision-making process [12, 13]. As was noted by the US National Research Council [3, p. 87], behavior based on the assumption that risk analysis is a matter for experts only, “may lead some of the interested and affected parties to feel disenfranchised from the regulatory process and either withdraw from the policy arena or seek unconventional ways to interfere with the process.”

Overall, the benefits associated with a participatory risk decision-making process are irrefutable. Most agencies dealing with the management of risks have acknowledged (through voluntary and/or regulated means) their responsibility to enable stakeholders to actively participate in the process. Likewise, stakeholders are increasingly aware of their right to be part of an informed process.

Successful Stakeholder Participation

Much has been written on “lessons learned” about past stakeholder (particularly public) participation efforts [8, 13–16]. While it is generally agreed that more research is required to evaluate all the elements that may contribute to a successful participatory process, it has been amply demonstrated that a variety of approaches can be employed [17]. It has also been clearly shown that a “one size fits all” approach for participation processes is neither feasible nor desirable. Each situation must be assessed in terms of the goals of participation, the design of the process and the context of the specific risk situation [18].

However, some general guidance may be found in the “Guidelines to Stakeholder Involvement” developed by the US Presidential/Congressional Commission on Risk Assessment and Risk Management [19]. Additional guidance can be found in Jardine *et al.* [20]. These considerations (modified from both sources) are summarized below:

- Stakeholder participation must be meaningful. Agencies should only involve stakeholders in the process if they are willing and able to respond to stakeholder input in making the final risk decisions. Involving stakeholders when the decision has already been made is unethical and only serves to increase frustration and distrust.
- Attempts should be made to engage all interested and affected parties so that a variety of perspectives are considered. If appropriate, stakeholders should be provided with incentives to ensure an “equal playing field” – for example, if agency personnel are being compensated to participate in the process as part of their jobs, it may be only fair for other stakeholders to receive some recognition of their time and expertise.
- Involvement of all parties should occur at the beginning of the process when the problem is defined. Failure to involve people at this stage in the process frequently results in either “solving the wrong problem” or in overlooking some key aspect of concern.
- The purpose of the process, the roles of those involved, and the design of the process should be clearly explained and agreed upon by everyone involved in the process.
- All interested and affected parties should have equal access to relevant information and support a mutual learning environment. Where possible, stakeholders should be empowered to make decisions by providing them with whatever resources are necessary to help them fully gather and understand all the relevant information.
- All parties should be willing to participate and work together. They must be prepared to be flexible, to negotiate, to listen, and to learn from different viewpoints.
- All those involved in the process should be given credit for their roles in the final decision. Too often, the coordinating agency takes full credit for the work of many stakeholders.
- Stakeholder involvement should be made part of the agency’s mandate and mission. Sufficient resources (including time) must be allocated to ensure that the process is initiated early and sustained through to the final risk-management decision.
- The “nature, extent, and complexity of stakeholder involvement should be appropriate to the scope and impact” [19, p. 16] of the risk problem and decision. For decisions that affect many people and/or are highly contentious, a formalized process involving all potentially interested and affected parties is warranted. For decisions with minimal impact and/or potential controversy, a more informal process of those directly involved might be more appropriate.

Table 1 Stakeholder participation goals and criteria for evaluating success in risk decision-making processes^(a)**Goal 1: Incorporating different values into decisions**

How much influence are the various stakeholders having on decisions made?

Whose values are represented?

Are the participants representative of the group they are representing?

Are all the interests at the table?

Are processes in place for soliciting input from interested and affected parties not at the table?

Goal 2: Improving the substantive quality of decisions

Are stakeholders improving decisions through creative problem solving, innovative ideas, or new information?

Are the decisions superior to likely alternatives in terms of cost-effectiveness, joint gains, the opinions of participants, or other measures?

Do participants add information, provide technical analysis, contribute innovative ideas, or contribute a holistic perspective?

Goal 3: Resolving conflict among competing interests

Was conflict that was present at the beginning of the process resolved by the end?

Was conflict avoided by avoiding contentious issues?

Was conflict avoided because certain parties were excluded or chose not to participate?

Goal 4: Building trust

Was mistrust of agencies or of interest groups that was present at the beginning of the process lessened by the end?

If trust was high at the beginning of the process, was this maintained or did it decrease?

Goal 5: Information exchange

Did all stakeholders learn enough about the issue to actively engage in decision making?

Was there educational outreach to the wider public?

Did the agencies involved learn and acknowledge both public concerns and values, and local knowledge of the environment and the community?

Evaluating Stakeholder Participation

As with risk communication, evaluation is a valuable but often overlooked component of stakeholder involvement processes (*see Evaluation of Risk Communication Efforts*). Without evaluation, there is no means of determining if the stakeholder participation process has been successful. Learning from successes and failures improves subsequent efforts. Conducting an evaluation is dependent on setting appropriate goals at the outset of the process. Beierle and Cayford [4] outlined five general goals for stakeholder participation. These are summarized in Table 1, together with criteria for evaluating if the participation process has been successful in meeting each goal.

Summary

Despite the acknowledged challenges in involving stakeholders in risk decision processes, the demonstrated benefits are incontrovertible. Furthermore, people have the right to be able to participate in

decision that affect them and the people they love; particularly when such decisions are based upon uncertain evidence. However, all parties would agree that one of the biggest obstacles in the employment of stakeholder participation and deliberation in risk decision-making processes is how this may be best undertaken. The “right” process of participation will need to be determined on the basis of the nature of the risk and the impact of the decision.

As a word of caution, stakeholder involvement should not be expected to necessarily prevent or end controversy. However, if properly employed, effective participation of interested and affected parties should result in productive discussion of disputes, and will hopefully engender the negotiation and compromise required to develop a decision acceptable to all.

Role of Risk Communication in a Comprehensive Risk Management Approach

CYNTHIA G. JARDINE

Statistical Arbitrage

Historical Context

In the 1960s, there were two basic approaches to stock-market analysis and investment strategies: fundamental analysis and technical analysis. *Fundamental analysis* (or value investing) was best exemplified by Graham and Dodd [1, 2]. Fundamental analysis focused solely on evaluation of the strength of the company as exhibited by its balance sheet, the strength of the industrial sector within which the company operated, and the economic outlook for the market as a whole and the company's sector in particular. Graham and Meredith [3] tried to educate the reader in the art and science of reading and interpreting financial statements. The result of this analysis was the identification of *value stocks* and *overvalued stocks*. The intelligent investor's portfolio would be long in the value stocks and short in the overvalued stocks (although Graham was not one to advocate short selling). Since the publication of Graham's books, value investing has been a standard approach to investing and is buttressed by an army of stock and industry analysts in all investment banks and brokerage houses; however, the method has periodically gone into and out of favor.

Technical analysis is, perhaps, best exemplified by Edwards *et al.* [4], whose work was first published in 1948 by Edwards and Magee, and is now in its eighth edition. Technical analysis is applied to the time series of stock prices and possibly also trading volume. The methodology assumes that stock prices are driven by supply and demand, and that certain stock prices, or at least trends, can be predicted from the history of that stock's time series of prices and trading volume. Interestingly, Edwards and Magee paid no attention whatsoever to the balance sheet, nor to any fundamental analysis of the company, industrial sector, or the economy. The buy and sell decisions were based solely on the stock-price pattern. More recent books on technical analysis have advocated combining it with fundamental analysis for stock selection.

The world of stock-price prediction entered a new phase in 1965 with the publication of Samuelson [5]. This was followed by the seminal paper of Fama [6], which coined the term *efficient market hypothesis* (EMH). This hypothesis is often defined

only informally. The interested reader might look at the website <http://www.e-m-h.org> for a brief history, various definitions, and relevant references. Fama [6, p. 383] gives the following description of the EMH:

... and investors can choose among the securities that represent ownership of firms' activities under the assumption that security prices at any time "fully reflect" all available information. A market where prices always "fully reflect" available information is called "efficient".

Fama [6, p. 383] goes on to conclude that "with but a few exceptions, the efficient markets model stands up well". This would mean that one can ignore the entire history of the stock-price time series (and that of all other stocks as well), paying attention only to current prices, and one will do as well as an individual who engages in fundamental or technical analysis.

The EMH is certainly counter intuitive and not easily believable; however, extensive empirical studies were conducted, and it was not rejected, at least for a substantial period of time. It was the dominant approach taken by the academic community for many years.

Malkiel's book [7] (now in its 8th edition) is one that was to become very popular in the mainstream press. Malkiel has been a constant, strong voice supporting the EMH (which he calls the random walk hypothesis). More recently, Malkiel [8] asserted:

The way I put it in my book, *A Random Walk Down Wall Street* first published in 1973, a blind-folded chimpanzee throwing darts at the *Wall Street Journal* could select a portfolio that would do as well as the experts. Of course, the advice was not literally to throw darts, but instead to throw a towel over the stock pages—that is, to buy a broad-based index fund that bought and held all the stocks in the market and that charged very low expenses.

The next 20 years might be called the *era of the efficient market Hypothesis*; however, there have been many attacks on it. Furthermore, the EMH did not seem to deter financial institutions from employing stock and industry analysts and selling information. Finally, many notable Wall Street figures rejected the EMH. For example, in an interview on April 3, 1995 issue of *Fortune* magazine, Warren Buffett said, "I'd be a bum in the street with a tin cup if the markets were efficient".

Beginning in 1985 and continuing well beyond 2000, there were a number of papers in the academic literature that called into question the EMH and assessed investment and trading strategies that could result in excess profit beyond market returns. It is, in fact, very easy to find many publications, especially in the popular press, which provide investment and trading strategies that appear to offer phenomenally good results. Many of those publications do not provide sufficient information about the details of the strategy, so that they are impossible to replicate. Others do not use sound statistical methodology for example, not realizing that strategies that are developed using in-sample data must be cross validated while using out-of-sample data. Finally, many papers do not make any assessment of the risks associated with the strategy they propose or investigate.

Arbitrage, Statistical Arbitrage, and Trading Strategies

Is “Riskless Arbitrage” Truly Riskless?

The concept of arbitrage is closely related to the “law of one price” which asserts that if two assets have the same payoff in every state, then they must have the same price. Going further, if two assets have the same payoff, but not the same price, then a riskless profit can be obtained by simultaneously trading both assets. Such a trade would be a *riskless arbitrage*. It is generally accepted that market forces will ensure that prices converge to their equilibrium levels, and the law of one price will be reestablished.

The reader should realize that there are few true arbitrage opportunities that exist. One situation occurs when the same instrument is priced differently in different markets. Shleifer and Vishny [9] give an example of two Bund futures contracts to deliver DM250 000 in face value of German bonds at a future time T , traded on two different markets. They suppose that the two identical contracts have different prices: one sells for DM240 000 and the second for DM245 000. An arbitrageur sells the higher priced contract and buys the lower priced one. Although he is perfectly hedged at time T , he must put up good faith money for each contract. If the prices of the contracts diverge further before time T , the arbitrageur must invest more money in the meantime. Depending on the extent to which such movements continue, he runs the risk of having to liquidate his

position at a loss prior to realizing the “sure profit” at time T . The authors go on to identify further complexities that bring forth other types of risks associated with even a simple “riskless” trade. Thus, the point they make is that even in the most obvious case of a pure arbitrage, opportunity risks may still be present.

Arbitrage-based pricing is exemplified by delta hedging and the Black–Scholes formula which leads to a unique price for the option, and if the price of the option were to differ, that difference presents an arbitrage opportunity. However, readers must be aware that this unique price is calculated under the assumption of a specific model, and if the model is wrong, then the price is wrong, thus the arbitrage opportunity is not free of risk, in this case *model risk* (see **Model Risk**).

Finally, default (see **Default Risk**) and credit risk (see **Mathematical Models of Credit Risk**) have entered the picture. With the failure of long-term capital management and with many other corporate defaults, it became apparent that the standard riskless arbitrage model needed to be extended to consider the possibility of *default risk*.

What Is Statistical Arbitrage?

Statistical arbitrage uses market models or statistical models to identify instruments that, according to the models, are priced inconsistently and whose prices are expected to return to what the models predict.

Hogan *et al.* [10, p. 526] say “We define statistical arbitrage as a long horizon trading opportunity that generates a riskless profit”. More precisely, they let $v(t)$ represent the discounted cumulative profits from a zero-initial-cost, self-financing trading strategy. The strategy is called a *statistical arbitrage* if the following three conditions hold:

$$\lim_{t \rightarrow \infty} E[v(t)] > 0 \quad (1)$$

$$\lim_{t \rightarrow \infty} \Pr[v(t) < 0] = 0 \quad (2)$$

$$\lim_{t \rightarrow \infty} \frac{\text{Var}[v(t)]}{t} = 0 \quad (3)$$

The authors then develop statistical tests that can be used with historical data to test whether specific strategies meet the definition of statistical arbitrage.

In this article, we think of statistical arbitrage in the following way. While arbitrage involves the trading of instruments that are identical or equivalent (e.g., a call and the hedging portfolio that replicates the call), but that have inconsistent prices, statistical arbitrage involves trading instruments that are different, but whose prices are mutually inconsistent according to some market model or historical price analysis. The price inconsistencies are identified by statistical techniques applied to historical data. A statistical arbitrage trading strategy places a set of trades on the inconsistently priced instruments, expecting those prices to return to their historical relationship. The statistical methods focus on the identification of *persistent anomalies* that violate the efficient market hypothesis, which can be used to create a trading strategy to generate profit with high probability.

The reader should be aware that there is no single widely accepted definition of statistical arbitrage. Indeed, the term is often used to connote a specific trading strategy, usually *pairs trading* (see section titled “Pairs Trading”).

Specific Trading Strategies

The focus of this section will be on some of the major statistical arbitrage strategies. These will include pairs trading, momentum, value and contrarian trading strategies, volatility trading, and technical analysis. In addition, we will introduce the concept of cointegration, originated by Engle and Granger [11], to broaden the concept of correlation, and we will see how it applies to pairs trading.

Pairs Trading

Suppose that an asset price process is governed by a mean-reverting process given by

$$dS_t = \alpha(\bar{S} - S_t) dt + \sigma(S_t) dW_t \quad (4)$$

where $\sigma(S_t)$ is some volatility function. Thus in the long run, the asset has an average price of $\bar{S}$. If the price at time t , S_t , is above $\bar{S}$, then a trader could short this asset in the expectation that, if the price process continues to be governed by this mean-reverting process with level $\bar{S} < S_t$, he or she will be able to sell and close the position at $\bar{S}$, thus

making a profit. Conversely, if the current asset price, S_t satisfied $S_t < \bar{S}$, then a trader could go long in the asset, expecting to close the position at $\bar{S}$, again making a profit.

We don't expect stocks to follow such a mean-reverting process (or, indeed, to be stationary); however, a pairs trader looks for a pair of stocks whose price difference or a weighted and shifted linear combination of which (to account for location and scale differences) follows a mean-reverting process. If one can find such a pair, then when the price of one of the two (say stock A) is high relative to the price of the other (say stock B), then a pairs trader would short a suitable amount of stock A and go long in a corresponding amount of stock B. When the prices of the two stocks go back into balance, then the trader closes the position. A pairs trading strategy can be an example of a *market neutral strategy*, one whose profitability does not depend upon the direction of the market. Rather it depends upon prices reverting to their long run equilibrium values relative to each other, not with respect to the market. The success of pairs trading as a statistical arbitrage strategy is evaluated in [12].

Pairs trading sounds like a “sure thing,” but there are several questions that need to be addressed:

- *how to find stocks A and B with this long run mean-reverting property?*
- *when to put on the position?*
- *how much of each stock to buy?*
- *when to close the position?*

One naïve approach to pairs trading is to calculate the correlation between all pairs of the price series. One would then trade those pairs with the highest correlations, whenever the price series diverged sufficiently. However, there is no justification for assuming that the difference between the two price series is stationary, hence new methodology is needed to handle this more general situation. This brings us to cointegration, which we discuss next.

Cointegration

Cointegration was developed by Engle and Granger [11] as a means of modeling dynamic codependencies in multivariate time series. While several individual series may themselves be nonstationary, we say

that they are *cointegrated* if we can find a linear combination that is stationary. This topic generalizes the notion of correlation, and an elementary discussion can be found in [13, Chapter 12]. Other good sources of information about cointegration and statistical tests for it include [14, 15].

A pairs trader would seek pairs (or triples, etc.) of stocks that are cointegrated. When the stationary linear combination of prices deviates far from its mean, a position could be opened with the amounts of each stock determined by the coefficients of the linear combination. When the stationary linear combination returned close to its mean, the position could be closed. One could also close a position at a loss if further deviation of the stationary linear combination from its mean appears to suggest that the stationary relationship between the stocks has changed.

Value and Contrarian Strategies

Value and contrarian strategies are based on fundamental analysis. One considers the intrinsic value of a stock and compares it with its market value using, for example, its book-to-market or P/E ratio as an indicator. A stock with a high book-to-market value is considered to be undervalued (and is a candidate for purchase in a value trading strategy), whereas a stock with a low book-to-market value is considered to be overvalued (and is a candidate for short selling in a value trading strategy). Such a strategy is also called *contrarian* as it favors purchase of stocks with share prices that are relatively low or which are “out of favor,” while it shorts stocks that are in favor.

DeBondt and Thaler [16] were among the first to show systematic anomalies in that “loser portfolios” (those with stocks that are out of favor) consistently outperformed the market. Conversely, “winner portfolios” (those with stocks that had recently outperformed the market) subsequently did much worse than the market. The authors related this phenomenon to “investor overreaction,” and cited principles of behavioral decision theory to justify their theory. Subsequent studies for the next decade would cite this paper and relate their work to it.

This work was significantly strengthened by Lakonishok *et al.* [17] who continued the ideas and considered trading strategies that went long in “value stocks” and short in “glamor stocks”. Membership in these two categories was defined in terms of some financial ratios including book to market, cash flow

to price, and P/E ratio. The authors clearly showed that this strategy led to returns in excess of market returns. They also dealt with the question whether the strong performance of the strategies was the result of their being inherently more risky.

Momentum Strategies

Everyone has heard the advice “buy low, sell high”. Momentum strategies follow the maxim “buy high, sell higher”. Suppose there is some sort of positive news (e.g., unexpectedly high earnings) that cause a company’s stock price suddenly to rise. Momentum strategies are based on the idea that the stock-price process will exhibit “momentum” and will rise even higher. Of course, there is a question as to whether there is any momentum effect at all, but if there is, the trader needs a stopping strategy to lock in the hoped for profits from additional price increases. Interestingly, a momentum trading strategy would seem to be essentially the direct opposite of the contrarian/value strategies discussed above.

The following papers utilize momentum strategies; however, the ways in which the portfolios are selected are different: [18–21]. These papers show overall that momentum-based strategies can lead to excess returns. The strategies that these authors use begin with a criterion defining momentum such as returns over a specific past period or closeness to the high price over a past period. They then study portfolios that are long in the stocks (or groups of stocks) that have high values of the momentum criterion and short in the stocks that have low values. There is also a position that argues against the efficacy of momentum strategies. Two such papers are [22, 23]. Among other things, they raise the issue of transaction costs. Their thesis is that the momentum strategies defined by the other authors show excess profits only because the transactions costs are ignored or understated.

Volatility Arbitrage Trading

The price of an option on an underlying tends to increase with increasing volatility of the underlying. One can take the formula for an option price together with the current option price and infer the value of the volatility (called the *implied volatility*). It is, however, possible that one may also have independent estimates of volatility, and those estimates may differ from the implied volatility. Popular ways to

estimate volatility range from naïve sample standard deviations of log returns to ARCH, GARCH, and EGARCH models, and the reader is referred to [13] for descriptions of these methods.

If, for example, the implied volatility is higher than the estimated volatility, then one would say that the option is overpriced with respect to the estimated volatility. This would lead a trader to short an option (or write an option) at the current price. One could also create a delta neutral portfolio by buying delta shares of the underlying and shorting the option. Of course, if the estimated volatility were to be larger than the implied volatility, then one would infer that the option is relatively underpriced and want to go long in the option and short in the stock. Strategies of this type, are discussed by Connolly [24]. Another type of volatility trade is a *straddle* in which one buys (or sells) both a call and a put option on the same underlying at the same strike with the same maturity. Straddles provide partial hedging against market movements. Noh *et al.* [25] do a study of methods for estimating volatility and compare them on the basis of how they would be used when choosing which straddles to invest in.

Market Factors

One of the classic studies that identified persistent anomalies is published in [26, 27] by Fama and French.

The abstract from [26] summarizes the results of this study:

This paper identifies five common risk factors (*see Integration of Risk Types*) in the returns on stocks and bonds. There are three stock-market factors: an overall market factor and factors related to firm size and book-to-market equity. There are two bond-market factors, related to maturity and default risks. Stock returns have shared variation due to the stock-market factors, and they are linked to bond returns through shared variation in the bond-market factors. Except for low-grade corporates, the bond-market factors capture the common variation in bond returns (*see Mathematical Models of Credit Risk*). Most important, the five factors seem to explain average returns on stocks and bonds.

Although multiple factors are cited, the work is most closely associated with company size in that stocks of small firms generally outperform stocks of large firms. A generalization of the Fama and

French factors was introduced by Carhart [28]. This paper adds a fourth factor, momentum, to the three stock-market factors identified by Fama and French. Furthermore, this paper is also interesting, because it looks at the performance of mutual funds.

Analysis of Trading Strategies

An important consideration, in addition to identifying potentially profitable trading strategies, is providing broader assessments of those strategies and statistical arbitrage in general. Some papers that have attempted such evaluations include [29, 30].

While considering trading strategies, one should also be cognizant of a variety of practical issues that can have a significant impact on their performance; however, some of these are not addressed in the various papers cited above. These might be grouped into four broad categories:

- *Transaction costs*

This category would include factors such as the charge to execute the trade, the price at which the trade is executed (i.e., bid-ask spread), the cost of odd-lot transactions, and fractional shares. An additional issue is the liquidity of the stock, and whether a purchase will influence the execution price. Lack of liquidity was a crucial ingredient in the failure of long-term capital management as described by Lowenstein [31].

- *Position holding costs and tax consequences*

Many trading strategies create portfolios that have both long and short positions. There can be additional costs to hold short positions. There are also tax consequences associated with trading strategies that can be difficult to evaluate and are largely ignored.

- *Survivorship bias*

Many of the papers mentioned above implement their strategies over a relatively long time period. Often the strategy is applied to a large set of stocks that have been listed continuously over the time period in question. This creates a survivorship bias, since stocks that go out of existence tend to be from companies that perform relatively poorly and go bankrupt or are acquired (*see Default Risk*). When one restricts an evaluation to stocks that survived over the time period in question, one is generally biasing the performance upward.

- *Riskiness of the strategy*

It is possible that a trading strategy might deliver excess profits, but do so because the strategy assumes higher than the market risk. One must control for the riskiness of the strategy.

Technical Analysis

In the academic literature, technical analysis has been considered to be nonsense. For example [7, p. 159] stated that “chart reading must share a pedestal with alchemy”. The assessment of technical analysis given in [7, Chapters 5 and 6] is scathing. However, in more recent times, computer-based techniques drawn from data mining or machine learning have become more popular, and these might be considered to be the twenty-first century version of technical analysis.

We cannot begin to describe here the many technical indicators that are available. They range from simple patterns such as a succession of three up and down cycles in which the middle cycle rises higher than the two outer cycles (head-and-shoulders) to complicated patterns in which the difference of two exponentially weighted moving averages is compared with a moving average of the difference (moving average convergence divergence). Technical indicators generally signal trades for one security at a time, rather than for pairs or large market portfolios.

A serious academic study of technical analysis was done by Lo *et al.* [32]. The authors automate many of the subjective choices for which technical analysis is criticized, and apply their automated procedures to US stocks from 1962 to 1996 and five pairs of technical indicators. They find that returns following the occurrence of one of the indicators do tend to be different from the returns of purchases that ignore the indicators. A critical discussion of this paper appeared in the same journal: [33]. Bauer and Dahlquist [34] describe 120 technical indicators, and do a systematic comparison of the signals that they generate to buy-and-hold strategies.

Statistics for Environmental Justice

Definition and Background

The United States Environmental Protection Agency (USEPA) defines the term *environmental justice* as "... the fair treatment and meaningful involvement of all people regardless of race, ethnicity, income, national origin or educational level with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies. Fair treatment means that no population, due to policy or economic empowerment, is forced to bear a disproportionate burden of the negative human health or environmental impacts of pollution or other environmental consequences resulting from industrial, municipal, and commercial operations or the execution of federal, state, local, and tribal programs and policies" [1].

This definition formalized a growing grassroots movement addressing the distribution of environmental hazards across sociodemographic groups, initially questioning whether hazardous waste sites or toxic facilities were disproportionately sited in areas with high minority populations. The movement began with local activists in the late 1970s and early 1980s and received national attention with the release of a 1987 report by the Commission for Racial Justice of the United Church of Christ (UCC) [2] following up on efforts beginning in 1982 in Warren County, North Carolina regarding the siting of a proposed polychlorinated biphenyl (PCB) disposal landfill in an area with a large proportion of African-American residents. In response to the UCC report, an earlier government study [3], and the efforts of the "Michigan Coalition" [4], the US EPA formed an Environmental Equity Working Group in 1990, and the EPA Office of Environmental Equity in 1992, which is now known as the *EPA Office of Civil Rights*.

In order to consider quantitative assessments of environmental justice, it is necessary to understand its regulatory setting. In 1994, President Clinton issued Executive Order 12898 requiring each federal agency to "analyze the environmental effects, including human health, economic, and social effects" of federally sponsored programs. For a more detailed historical development, see [5] and [6], and for the

complete text of Executive Order 12898, see [7]. In effect, Executive Order 12898 links two earlier pieces of legislation, namely, the National Environmental Policy Act (NEPA) of 1969 [8] and Title VI of the Civil Rights Act of 1964 [9]. NEPA established the regulatory requirement of an environmental impact statement (EIS) for all federally sponsored activities "significantly affecting the quality of human environment" and the inclusion of any socioeconomic impacts related to significant changes in the physical environment. Title VI of the Civil Rights Act prohibits any recipient of federal funds from taking action that results in a discriminatory impact on the basis of race, sex, color, national origin, religion, age, or disability. If a recipient of federal assistance is found to have discriminated and voluntary compliance cannot be achieved, the US Department of Justice is allowed to initiate fund termination or other legal action. Liu [6] points out that NEPA is associated with proposed future environmental impacts while Title VI pertains to past, present, and future actions and decisions by any entity receiving federal assistance.

Executive Order 12898 places environmental justice within the same legal setting as other nondiscrimination issues and, as a result, links environmental justice assessments to ongoing judicial and legislative interpretations and opinions regarding the standards of evidence required to assess Title VI complaints. We note that, while the general conceptual issues of environmental justice apply to any population subgroups, most assessments of environmental justice to date default with respect to legal and regulatory issues involving subgroups covered under Title VI and Executive Order 12898, i.e., age, race, income, but particularly race.

The legal and regulatory definitions of environmental justice provide the background for guidelines and proposals for investigative procedures to address complaints. Of particular interest to quantitative risk assessment is the role of statistical summaries and measurements. In other words, what does one need to quantify in order to demonstrate environmental injustice?

The US Department of Justice outlines several key legal concepts and the role of statistical evidence in investigating Title VI complaints [10]. A key distinction is that between "intentional discrimination/disparate treatment" where similarly situated persons (individuals or classes) are treated differently

intentionally, and “disparate impact/effects” where persons are treated differently with or without intent by another party. Proving “intentional discrimination” requires the complainant to prove both disparate impacts as well as the intent behind them. Proving “disparate impact” does not require intent and, in fact, may be the result of a “neutral policy or practice that has the effect of disproportionately excluding or adversely affecting members of a protected group” [10]. Past rulings of the US Supreme Court have upheld a “disparate impact” standard for proving Title VI violations in general [11, 12] with similar supporting decisions from lower courts.

Proving disparate impact often relies on statistical evidence and the US Department of Justice specifies the role of such evidence by stating “If: evidence reveals a statistically significant difference in the treatment of similarly situated classes of different races (or sexes) in the delivery of services (or receipt of benefits, in employment levels, etc.), and there is no legitimate nondiscriminatory reason for the observed pattern of disparities, then it is reasonable to infer that race was a factor in creating such a pattern” [10]. The US Department of Justice Title VI Investigative Manual next stresses that statistical techniques are required to demonstrate that “substantial disparate impact exists and that the observed impact is statistically significant” [10].

Most legal and research investigations of environmental justice focus on measuring disparate impact in environmental exposures rather than disparate impact in subsequent outcomes related to the exposure. A focus on outcomes complicates analysis since it would require one to show differences between subgroups with respect to both exposures and outcomes, and to show that the observed outcome difference is caused by the exposure difference.

Data Sources

Typical assessments of environmental justice in the United States utilize data from at least two sources: demographic profiles for small enumeration areas (e.g., census tracts or block groups) and exposure estimates across a study area of interest. Both values vary across space, leading to a central role for geographic information systems (GISs) in environmental justice assessments [6] (*see Geographic Disease Risk; Hotspot Geoinformatics*). Population demographics

often reveal higher local concentrations of minority and/or low-income populations, and investigation hinges on whether these local concentrations are associated with local concentrations of high exposure to environmental hazards.

Reliable demographic data are obtained from census projections, but sources of environmental exposure data vary from study to study. In some cases, only the location of the source (proposed or actual) is known and exposure estimates are based on approximated or modeled values based on actual or estimated releases from the source. Few assessments use monitored or measured exposure values since many assessments (consistent with the link to EIS preparation) are in response to planned rather than existing sources of environmental hazard (*see Environmental Monitoring*).

Statistical Methods

When summarizing statistical methods for environmental justice assessments, two broad categories of comparisons emerge based on the availability and/or extent of exposure data. In the absence of measured or approximated exposure values, the first set of comparative methods revolves around proximity-based exposure classifications. Such classifications may be based on simple distance radii with individuals residing within a given radius classified as exposed and those residing outside of the radius classified as unexposed. More sophisticated options are also available within GISs such as classifications based on travel times or distances along road networks, but the general principle is the same. In this setting, one assesses environmental justice by comparing population demographics across exposure classes. For instance, one could compare the proportions classified as African-American for individuals residing in the exposed and nonexposed areas. Such applications are very common in the environmental justice literature, and allow assessments using only locations of hazards rather than measured exposure values. However, many reports illustrate that such approaches can lead to very different conclusions for different exposure-defining radii, partially due to geographic heterogeneities in the distribution of demographic subpopulations (e.g., the population within 1 mile of a proposed site location might contain a majority of one racial group while the population

within 3 miles contains a majority of another group) and also potentially due to confounding variables impacting both demographics and exposure (e.g., land values, neighborhood average incomes) [6, 13–15]. The confounding issue may be addressed, at least in part, through the use of regression-based methods measuring associations between population proportions and exposure classifications while adjusting for other covariates. Greenberg [13] and Liu [6] discuss the advantages and disadvantages of regression-based methods to adjust associations between subpopulation proportions and exposure classification for potentially confounding factors. Such analyses will adjust the measured associations but are still subject to the selection of the exposure-defining classification, and to the effects of potential collinearities between covariates such as race and income.

The second set of comparative methods involves quantitative exposure values or surrogates. As noted above, many environmental justice studies involve planned or potential exposures or emissions rather than measured ambient or personal exposures. As a result, very few published environmental justice assessments make use of monitored exposure data, and most utilize some sort of proximity-based exposure surrogate. Once one has obtained exposure measures (e.g., through ambient or personal monitoring) or exposure surrogates (e.g., based on proximity) for each individual or census subregion, one defines comparison groups by the subpopulations of interest (e.g., racial or ethnic groups), and then compares the distributions of exposure measurements or surrogates between these groups. Such comparisons are appealing in that comparisons of exposures between demographic subgroups seem to coincide better with the question of interest than do comparisons of demographics between exposure groups. Comparisons of exposures (or exposure surrogates) could be straightforward two-sample tests comparing means or medians, or could involve comparisons of the exposure distributions for each subpopulation using tests such as Kolmogorov–Smirnov tests, probability plots, relative distribution functions [16], or integrated cumulative exposure distributions [15].

The key factors in deciding between comparisons of population structure across exposure surrogate groups and comparisons of experienced exposure surrogates across population groups appear to be data availability and justification of a single exposure or set of exposures of interest. In the case

of monitored ambient exposures, measurements may be unavailable for the time periods of interest for retrospective studies of existing hazards, or simply not in existence for proposed future sources of hazard. If, as is usually the case, exposure data are not available, proximity-based measures often act as surrogates either for exposure classification (the radius-based classification) or as exposure surrogates themselves (e.g., inverse-distance approximations [15]). In some cases, some exposure measurements may be available, but the driving justification for a particular assessment of environmental justice may be based on exposures to a collection of hazards (from a single or multiple sources) rather than to a particular measurable substance or substances. In such cases, various collective and/or cumulative exposure indices may be proposed or used, such as the population emissions index (PEI) [17], which is based on a weighted average of emissions within each population subgroup with weights based on population proportions within small enumeration districts.

In summary, environmental justice represents a maturing issue comprised of complex interrelated legal, regulatory, risk, demographic, exposure, and statistical issues. An appreciation of each of these areas provides a context for improved data collection, more accurate and reliable assessment methodologies, and appropriate responses.

Statistics for Environmental Mutagenesis

Laboratory experiments to assess the toxic potential of hazardous substances (*see What are Hazardous Materials?*) often generate data whose statistical analysis depends on the nature of the endpoint and the aspects of the particular assay under study [1]. Among major endpoints of risk analytic value, environmental damage to genetic components such as DNA is of increasing interest [2, 3]. Mutation induction, or *mutagenesis*, and other forms of genotoxicity due to environmental exposures represent fruitful areas of study, particularly as continuing biotechnological advances allow for more precise genetic study [4].

Mutagenesis is perhaps the most varied of any toxicological mechanism, since the potential components of genetic damage are so numerous. Indeed, there exist well over 100 different genotoxicological test systems, employing all sorts of animal and microbial systems [5]. Statistical themes associated with environmental mutagenesis experiments include proper identification of the statistical nature of the outcome data [6–10], construction of appropriate biomathematical models to characterize dose–response and other features of genetic damage [11–16], sample size determinations [17, 18], and the selection of statistical tests based on these models [19, 20]. An introduction to these various issues is given in the compilation by Kirkland [21] and the review by Edler [22]. Herein, attention will be directed at some of the basic issues of dose–response testing and analysis useful for risk assessments of environmental mutagens. For an informative article that emphasizes the risk regulatory questions associated with mutagenesis and genetic toxicity data, see Dearfield and Moore [23].

Microbial Systems in Environmental Mutagenesis: the *Salmonella* Assay

Perhaps the most well known of all modern mutagenicity assays is the Ames/*Salmonella* microsome assay [24], employing the bacteria *Salmonella*

typhimurium to identify damage to DNA after exposure to toxic environmental agents (*see Environmental Hazard*). The assay is based on strains of the bacterium unable to synthesize histidine, an amino acid required for growth. This production deficiency can be reversed into a production capability *via* point mutations at selected sites on the bacterial genome. DNA damage is indicated by mutation of the bacteria from histidine dependency to a self-sustaining state. Thus, the mutated cells can grow in a microenvironment (such as a petri dish) containing only minimal amounts of histidine; greater mutant yield at higher exposures to the environmental agent suggests that mutagenesis increases with increasing dose. Observational accuracy of the assay is enhanced by use of a selective medium for the growth environment, so that only mutant colonies grow after exposure to the environmental toxin.

The observations from this microbial assay are the mutated colony counts, Y_{ij} , for the j th replicate plate at the i th dose ($i = 1, \dots, T$; $j = 1, \dots, R_i$). Typically, the number of replicate plates is taken to be constant, e.g., $R_i = 3 \forall i$. Table 1 presents an example of data from a *Salmonella* assay, using the chemical agent 1,3-butadiene. A natural candidate for the sampling distribution of Y_{ij} is the Poisson distribution for count variables. Indeed, many processes that drive the Poisson process are active with the colony count data seen here. These include (a) the microbes' responses are independent, (b) each locally organized group of microbes experiences the same environment (ignoring controlled variables such as dose), (c) the plated number of microbes is large, say 10^8 , and (d) the probability that a plated microbe gives rise to a visible mutant colony, is small here, between 10^{-5} and 10^{-9} [14]. A fifth assumption crucial to adoption of the Poisson distribution is, however, that both the environment and the number of microbes plated should remain relatively stable across replicate plates (within a dose group). If this is not the case, extra-Poisson variability results, and one is forced to model or otherwise account for the consequent overdispersion in Y_{ij} .

Testing for Extra-Poisson Variability

Testing for extra-Poisson variability is critical when analyzing count data from environmental mutagenesis experiments. Standard trend tests for

Poisson-distributed counts become too sensitive in the presence of overdispersion, increasing type I error rates above the nominally specified α level [25]. Thus, the data analyst must be aware of the nature and level of any overdispersion in the data before selecting a test for dose–response.

Extra-Poisson variability in a set of ostensibly homogeneous observations is assessed *via* a variance-to-mean comparison. The test employs Fisher’s dispersion statistic [26, 27]:

$$X_i^2 = \sum_{j=1}^{R_i} \frac{(Y_{ij} - \bar{Y}_i)^2}{\bar{Y}_i} \quad (1)$$

where $\bar{Y}_i$ is the i th dose sample mean ($i = 1, \dots, T$). Asymptotically, X_i^2 is distributed as $\chi^2(R_i - 1)$, hence $X_i^2 > \chi_{1-\alpha}^2(R_i - 1)$ implies significant extra-Poisson variability. This test is $C(\alpha)$ -optimal [28] against the negative binomial distribution, a standard alternative to the Poisson model. To extend equation (1) to multiple test groups, simply aggregate the individual X_i^2 statistics into a sum: $X^2 = \sum_{i=1}^T X_i^2$. Asymptotically, X^2 is distributed as $\chi^2(\sum_{i=1}^T R_i - T)$. (A slightly more powerful test of extra-Poisson variability may be constructed using the similar statistic $C^2 = \sum_{i=1}^T \sum_{j=1}^{R_i} (Y_{ij} - \bar{Y}_i)^2 / \bar{Y}$, where $\bar{Y} = \sum_{i=1}^T R_i \bar{Y}_i / \sum_{i=1}^T R_i$ [29].) Dean and Lawless [30] discuss additional extensions to more complex regression settings; also see Kim and Park [31] and Xiang and Lee [32].

A common application of these tests is to large, controlled databases where similar control trials and replicate data are available. Margolin *et al.* [14] reported on such data, demonstrating that the Poisson model often inadequately describes statistical variability when analyzing *Salmonella* mutagenicity experiments. Further research has suggested that *Salmonella* data often exhibit extra-Poisson variability, and that the parent distribution of the data may be better described by a negative binomial distribution [19]. Other publications indicate, however, that the Poisson model can be acceptable in select instances [33], particularly for test data obtained by imposing strict protocol adherence and by harvesting all the data on the same day [34, 35]. Given these considerations, testing for extra-Poisson variability is of clear necessity when analyzing *Salmonella* dose–response data (see **Dose–Response Analysis**).

Trend Tests for Dose–Response

For mutagenicity experiments where no extra-Poisson variability is evidenced, the well-known Cochran–Armitage trend test for dose–response may be employed. Under Poisson sampling, the test is known to be optimal against any monotone dose–response function [36]. Given the observed counts Y_{ij} ($j = 1, \dots, R_i; i = 1, \dots, T$), and denoting x_i as some increasing score (dose, log-dose, etc.) associated with treatment level i , the test statistic is

$$Z_{CA} = \frac{\sum_{i=1}^T X_i \left[\left(\sum_{j=1}^{R_i} Y_{ij} \right) - R_i \bar{Y} \right]}{(\bar{Y} S_x^2)^{1/2}} \quad (2)$$

in which $S_x^2 = \sum_{i=1}^T R_i (x_i - \bar{x})^2$ and $\bar{x} = \sum_{i=1}^T R_i x_i / \sum_{i=1}^T R_i$. Asymptotically, Z_{CA} is distributed as standard normal, and significant dose–response is suggested when Z_{CA} is larger than an appropriate upper- α critical point from a standard normal distribution, z_α .

If the response is overdispersed and the Poisson model is invalid, a form of Cochran–Armitage trend test may still be constructed. Under a negative binomial parent model, one simply replaces $(\bar{Y} S_x^2)^{1/2}$ in equation (2) with an updated estimator based on estimating the negative binomial variance [19]. The result is

$$Z_{NB} = \frac{\sum_{i=1}^T x_i \left[\left(\sum_{j=1}^{R_i} Y_{ij} \right) - R_i \bar{Y} \right]}{[\bar{Y} (1 + \hat{\delta} \bar{Y}) S_x^2]^{1/2}} \quad (3)$$

The dispersion estimator, $\hat{\delta}$, is calculated *via* the method of moments, maximum likelihood, maximum quasi-likelihood, or more advanced techniques [37–40]. As above, significant dose–response is suggested when Z_{NB} is larger than a standard normal critical point, z_α .

When the parent distribution of the data is not known or indeterminate, it is possible to construct a generalized score statistic for testing trend [41].

Table 1 *Salmonella* mutagenicity results for 1,3-butadiene in strain TA1535

Dose (ppm)	Mutants per plate, Y_{ij}			Average plate count, $\bar{Y}_i$
0.000	20	31	27	26.0
0.002	100	92	89	93.7
0.007	147	123	178	149.3
0.014	216	170	181	189.0
0.020	176	154	183	171.0
0.030	154	153	149	152.0

This is

$$Z_{GS} = \frac{\sum_{i=1}^T R_i(x_i - \bar{x})\bar{Y}_i}{\sqrt{\sum_{i=1}^T R_i(x_i - \bar{x})^2 \sum_{j=1}^{R_i} (Y_{ij} - \bar{Y})^2}} \quad (4)$$

similar to the basic statistics in equation (2) or equation (3). Z_{GS} is distributed asymptotically as standard normal; significant dose–response is suggested when $Z_{GS} > z_{\alpha}$.

Trend Test under Nonmonotone Dose–Response

An important, additional feature illustrated by the data in Table 1 is a curious downturn in the response at higher doses. This form of nonmonotone dose–response is common in the *Salmonella* assay [42], and is often observed with other mutagenesis assays as well [43].

In *Salmonella*, the downturn phenomenon is driven by a number of possible mechanisms, the most common of which is a consequence of the experimental scheme employed to identify the mutational events. Since mutagenesis is identified by growth on a selective medium, any other mechanism that hinders growth will compete with the desired outcome. Thus, e.g., high exposures of the toxic agent can lead to cell death or perhaps chemical/threshold induced increases in DNA repair. These factors conspire to *reduce* the yield of mutated cells by killing or neutralizing the microbes before mutations can be observed. The result is a downturn at the higher doses, called an *umbrella response* [44]. As might be expected, simple tests for monotone trend such as Z_{CA} , Z_{NB} , or Z_{GS} can exhibit large losses in power to detect any increase in dose–response in the presence

of a downturn [41, 45], and suitable alternatives must be employed.

Nonlinear biomathematical and empirical models for this downturn phenomenon are available, which, when coupled with the negative binomial sampling model on the Y_{ij} 's, involve fairly advanced statistical methodology [46, 47]. A simple alternative is to identify statistically the point of maximal departure from background mutation levels, and then test for increasing trend up to that point. Various procedures have been suggested for such an approach [48, 49], the majority of which analyze the ranks of the observations *via* “nonparametric” techniques based on the ranks of the observations.

For example, a nonparametric approach developed by Simpson and Margolin [49] estimates recursively the point of maximal response (the *umbrella point*), and then tests for a significant increase in dose–response up to that point. One begins by calculating a series of two-sample Mann–Whitney statistics [50], W_i , comparing the i th dose group with – collectively – all preceding dose groups, starting at $i = T$ and working backwards. That is, W_T tests whether the response information at $i = T$ departs significantly above the pooled response information at $i = 1, \dots, T - 1$. If so, an estimate, h , of the umbrella index is $h = T$. If not, one discards the information at $i = T$, and repeats the process at $i = T - 1$. In this way, the test employs the values of W_i ($i = T, T - 1, \dots, 2$) to estimate the umbrella index *via* recursive pretesting. In effect, it selects this estimate as the largest dose index, h , such that W_h is larger than a specified critical value c_h ; i.e., $h = \max\{i \in \{2, \dots, T\} : W_i > c_i\}$, where $c_2 = 0$ and $c_i = c_i(q)$ ($i = 3, \dots, T$) is the q quantile of the distribution of W_i under the null hypothesis of no dose–response. The tuning parameter $q \in (0, 1)$ must be prespecified, and is usually set at or near $q = 0.5$ [45].

Once the umbrella index, h , is estimated, the recursive procedure calculates the conditional Jonckheere–Terpstra trend statistic $U_h = W_1 + \dots + W_h$ [51], and an increasing dose–response is suggested when U_h is larger than the $(1 - \pi)$ quantile of the distribution of U_i under the null hypothesis of no differences among the doses ($i = 2, \dots, T$), for $0 < \pi < 1$. For fixed q and prespecified significance level α , a conservative choice for π is $\pi = \alpha(1 - q)/(1 - q^{T-1})$. A computing algorithm for these calculations is described in Simpson and Dallal [52], and extensions and other research issues involved with rank-based testing for *Salmonella* data are discussed in Schumacher and Schmoor [42] and Cologne and Breslow [53]. Also see the review by Kim and Margolin [20].

Example: 1,3-Butadiene

Consider the example of the airborne toxin 1,3-butadiene, the data for which appear in Table 1. These values represent *Salmonella* mutagenic response after gaseous exposure to the chemical, where an increase in the number of observed colonies suggests a mutagenic effect.

Begin by testing whether the data exhibit any overdispersion, relative to the Poisson sampling model. Employing the aggregated dispersion statistic using equation (1) to the data in Table 1 gives $X^2 = 22.134$ on 12 df ($P = 0.004$). Strong departure from Poisson variability is evidenced. If the negative binomial sampling model were considered as an adequate replacement to the Poisson for these data, then a trend test for increasing dose–response based on equation (3) gives $Z_{NB} = 1.285$, with one sided $P = 0.099$. Marginal suggestion of an increasing trend is given.

For these data, however, a downturn in the dose–response is evident. This could affect the trend test’s ability to identify properly a positive dose–response. Application of the recursive test for umbrella response is therefore appropriate: setting the tuning parameter to $q = 0.5$, the umbrella index is estimated as $h = 6$, with corresponding rank-based trend statistic given by $U_6 = 105.5$. Rejection occurs at significance levels as low as $\alpha = 0.005$, providing strong evidence of a positive dose–response for these mutagenicity data.

Statistics for Environmental Teratogenesis

Background

Teratogenesis is a process through which embryo/fetal development is altered and an abnormality is induced. The abnormalities can arise from genetic or environmental factors. Any chemical or physical agents that can cause an abnormality in the embryo or fetus are called *teratogens*. Teratology is the study of adverse effects of environment on the developing system. The term *teratogenesis* specifically refers to the development of abnormal cells during embryo/fetal growth. In descriptions of the harmful effects of chemical or physical agents on the developing system, in a broader sense, developmental toxicology is the study of adverse effects on the developing organism that may result from exposure prior to conception (either parent), during prenatal development, or postnatal development to the time of sexual maturation. Reproductive toxicology is the study of adverse effects on the reproductive system of males and females, as well as on postnatal maturation and reproductive capacity of offspring, and the cumulative effects on generations. Adverse developmental and reproductive effects include effects on male and female fecundity, spontaneous abortion, infant and child death, congenital malformations, growth retardation, and mental retardation. Because of ethical and practical considerations, the major source of information for studying potential developmental and reproductive effects of chemicals on humans is generally the laboratory animal experiments (*see Cancer Risk Evaluation from Animal Studies*). Mice, rats, and rabbits are the commonly used species in developmental and reproductive studies.

Animal developmental and reproductive studies have been divided into three segments. These are referred to as *Segment I* (fertility and general reproductive studies), *Segment II* (teratology or developmental toxicity studies), and *Segment III* (perinatal and postnatal studies) [1]. The three segments of investigations are generally required by regulatory agencies in the preclinical testing of new drugs or environmental agents such as pesticides and

industrial chemicals. Testing protocols for pharmaceutical chemicals and nonpharmaceutical chemicals are similar; however, the data for nonpharmaceutical chemicals would be used to establish an acceptable level of exposure using quantitative risk assessment. Each animal is monitored throughout the experiment to detect toxic and pharmacologic effects of the test compounds. In a Segment II study, the pregnant dams are normally sacrificed just prior to term, and fetuses are then examined to assess developmental effects.

A developmental experiment typically consists of an untreated control and three dosage groups. The highest dose is chosen to produce minimal maternal toxicity, ranging from marginal body weight (BW) reduction to not more than 10% mortality. The low dose should be a no-observed-adverse-effect level (NOAEL) for both maternal and developmental toxicity. The mid-level dose is usually halfway between the low and high doses. A fourth dosage group may be added to avoid excessive dosage intervals and to assess dose-response relationships for quantitative risk assessment. The dose should ideally be the amount of active substance at the affected tissue site. The estimate of the internal tissue-site dose requires data from toxicokinetic and/or toxicodynamic experiments. In the absence of this information, the amount of the internal dose is assumed to be proportional to the administered or exposure dose. Typically, dosage is measured in milligrams per kilogram body weight per day. Animals can be assigned to dosage groups totally randomly or by stratified BW (but randomly within BW classes).

The developmental endpoints can generally be divided into two categories: parental and embryonic/fetal endpoints. Since the test chemical is administered to the adult animal, the adverse effect occurs in the female that receives the chemical or that is mated to a male that receives the chemical and the treatment affects the embryos/fetuses indirectly *via* the dam. Thus, the development of an individual embryo/fetus in a dam is not an independent process. The embryo/fetal responses from the same dam are expected to be more alike than responses from different dams. This phenomenon is referred to as the *litter effect*. The experimental unit in the analysis should be the litter with the embryo/fetal responses representing multiple observations from a single experimental unit. Failure to account for the intralitter correlations by using each fetus as the experimental unit can

underestimate the variance of an effect and reduce the validity of the analysis.

Statistical analyses of various developmental endpoints have been concerned with two aspects: qualitative testing for detecting adverse effects and quantitative estimation for risk assessment. The qualitative testing is to determine if there is a statistically significant difference between the control and dosed groups. The quantitative estimation is to determine a safe level of human exposure from an assessment of the dose–response relationship. The quantitative risk estimation is typically used for environmental or workplace exposures and does not apply to pharmaceutical drugs.

Dose–Response Experiments

Dose–response models are usually formulated to establish a mathematical relationship between the observed response and the dosage level (*see Dose–Response Analysis*). Risk assessment aims at deriving an acceptable level corresponding to little or no risk or estimating a risk at a given exposure level from a fitted dose–response function. The preliminary step is to generate dose–response data, typically from experiments in laboratory animals.

Consider an experiment of g groups, a control ($d_1 = 0$) and $g - 1$ dose groups ($d_2, \dots, d_g$). Assume that the i th group contains n_i female animals. Let y_{ijk} be the response from the k th fetus out of n_{ij} examined or tested for a particular developmental outcome, $1 \leq i \leq g$, $1 \leq j \leq n_i$, and $1 \leq k \leq n_{ij}$. Note that the y_{ijk} may be an indicator variable representing the presence or absence of a particular effect or a continuous variable representing a magnitude of the outcome. In dose–response studies, the mean parameters are of interest in terms of a marginal model. The mean parameters in a marginal model have a population-averaged interpretation in the sense that the effect of the dose (and other covariates) is averaged across the animals in the same dose group. It is commonly assumed that the mean responses within a litter are exchangeable [2] having a common mean $E(y_{ijk}) = \mu_{ij}$ and a common correlation $\text{Corr}(y_{ijk}, y_{ijk'}) = \phi_i$. The parameter ϕ_i is the intralitter correlation, and it may vary with dose. The mean parameter is related to the dosage level, dose–response function, and a set of covariates $\mathbf{z} = (1, d, z_3, \dots, z_p)$ (e.g., litter size or sex).

The first step in quantitative risk assessment is to select a dose–response function to fit the animal dose–response data. The dose–response function is governed by the nature of the measurement that represents the developmental endpoint of interest. Measurements for developmental toxicity endpoints can be divided into four types: (a) continuous (e.g., fetal body or organ weight), (b) dichotomous (e.g., presence or absence of a malformation), (c) ordered categorical (e.g., a histology score that ranges from 1 – normal to 5 – extremely abnormal), and (d) count (e.g., number of implantations). Quantitative risk assessment has focused on the continuous and dichotomous response endpoints.

Dose–Response Models for Continuous Data

For continuous response data such as a fetal BW, the fetus response y_{ijk} is expressed as a mixed-effects model with two sources of variations: the between litters γ_{ij} and within litters e_{ijk} ,

$$y_{ijk} = \mu_{ij} + \gamma_{ij} + e_{ijk} \quad (1)$$

The mean parameter μ_{ij} represents the fixed effects component. The random components γ_{ij} and e_{ijk} are independently normally distributed with $E(\gamma_{ij}) = 0$, $\text{Var}(\gamma_{ij}) = \sigma_a^2$, and $E(e_{ijk}) = 0$, $\text{Var}(e_{ijk}) = \sigma^2$. Thus, the mean and variance of y_{ijk} are $E(y_{ijk}) = \mu_{ij}$ and $\text{Var}(y_{ijk}) = \sigma_a^2 + \sigma^2$. The intralitter correlation between y_{ijk} and $y_{ijk'}$, for $k \neq k'$ is $\phi = \sigma_a^2 / (\sigma^2 + \sigma_a^2)$.

The mean parameter μ_{ij} can be modeled as a linear function of the dose and covariates, for example,

$$\mu_{ij}(d_i | n_{ij}) = \beta_0 + \beta_1 d_i + \beta_2 d_i^2 \quad (2)$$

The μ_{ij} may also be modeled by nonlinear function, such as the Hill model:

$$\mu_{ij}(d_i) = \beta_0 + \beta_1 \frac{d_i^n}{k^n + d_i^n}, \quad n \geq 1 \quad (3)$$

The maximum-likelihood estimation (MLE) of the parameters of the linear mixed-effects model (2) and the nonlinear mixed-effects model (3) are estimated using reweighted least-squares methods iteratively [3–5].

In quantitative risk assessment, dose–response models for continuous endpoints are often based on

the per-litter response. The fetal toxicity endpoints are analyzed in terms of the average within each litter $y_{ij} = \sum_k y_{ijk}/n_{ij}$. Since litter is the experimental unit, the y_{ij} represents a summarized measure of the fetal responses of the experimental unit. Note that y_{ij} can also be the measurement of the maternal endpoints (e.g., maternal body or organ weight). The y_{ij} has a normal distribution with the mean μ_{ij} . The MLEs of the dose–response coefficients are estimated by the least-squares or nonlinear least-squares method.

Dose–Response Models for Dichotomous Data

Let y_{ijk} indicate the presence or absence of a response. Assume that the mean and variance of y_{ijk} are $E(y_{ijk}) = \mu_{ij}$, and $\text{Var}(y_{ijk}) = \mu_{ij}(1 - \mu_{ij})$ and the correlation is $\text{Corr}(y_{ijk}, y_{ijk'}) = \phi_i$, where $k, k' = 1, \dots, n_{ij}$, and $k \neq k'$. The parameter μ_{ij} is the probability of a developmental effect for the j th litter in the i th group, and ϕ_i is the intralitter correlation coefficient. Parametric multivariate binary models have not been widely used in practice because their MLEs are difficult to compute.

A traditional modeling approach, in terms of the total number of responses, is based on the assumption of exchangeability within a litter. The total number of responses in a litter $y_{ij} = \sum_k y_{ijk}$ has the mean $E(y_{ij}) = n_{ij}\mu_{ij}$ and variance $\text{Var}(y_{ij}) = n_{ij}\mu_{ij}(1 - \mu_{ij})[1 + \phi_i(n_{ij} - 1)]$. The distribution of y_{ij} is a “generalized” binomial. The y_{ij} has an extra-binomial distribution if the intralitter correlation ϕ_i among y_{ijk} ’s is positive, and y_{ij} has a subbinomial distribution if ϕ_i is negative. If $\phi_i = 0$, then all y_{ijk} ’s are independent binary random variables and y_{ij} is a binomial.

The intralitter correlation coefficient is positive ($\phi_i > 0$) for most developmental toxicity endpoints. The beta-binomial model is the distribution commonly used for modeling data with extra-binomial variation. Under the reparameterization $\mu_i = a_i/(a_i + b_i)$ and $\phi_i = (a_i + b_i + 1)^{-1}$, the beta-binomial distribution is

$$P(y_{ij}) = \binom{n_{ij}}{y_{ij}} \frac{B(a_i + y_{ij}, b_i + n_{ij} - y_{ij})}{B(a_i, b_i)} \quad (4)$$

where $B(a_i, b_i) = \Gamma(a_i)\Gamma(b_i)/\Gamma(a_i + b_i)$ and $\Gamma(\cdot)$ is the gamma function, $a_i > 0$, and $b_i > 0$.

For dichotomous responses, the dose–response function $\mu_{ij} = P(d_i)$, relates the probability of

response to the dose. The mean function is often modeled by a logit link function, $\log[\mu_{ij}/(1 - \mu_{ij})]$, in which case the simple linear logistic Dose–response model is

$$P(d_i) = \frac{\exp(\beta_0 + \beta_1 d_i)}{1 + \exp(\beta_0 + \beta_1 d_i)} \quad (5)$$

The logit model (see **Logistic Regression**) has the advantage that the coefficients have the interpretation of being log odds ratios. Chen and Kodell [6] proposed a Weibull dose–response model:

$$P(d_i) = 1 - \exp(-\beta_0 - \beta_1 d_i^w) \quad (6)$$

The power parameter on dose, $w > 0$, increases the flexibility in the shape of the dose–response function. The dose–response model $P(d)$ can include any additional explanatory variables (e.g., fetal weight, litter size). For example, Kodell *et al.* [7] generalized the Weibull model (6) by incorporating the litter size:

$$P(d_i) = 1 - \exp[-\beta_0 - b_1 n_{ij} - (\beta_1 + b_2 n_{ij})d_i^w] \quad (7)$$

For the dichotomous data, the intralitter correlations typically are either modeled as constant across groups or modeled separately for each group. When intralitter correlations are dose dependent, the use of a common intracluster correlation in the beta-binomial model fitting might bias the estimation of dose–response coefficients [8]. On the other hand, the estimates obtained from the fitting of separate correlation parameters might not be reliable [8]. Bowman *et al.* [9] proposed using a logistic dose–response model to fit the intralitter correlations.

The quasi-likelihood approach [10] is an alternative approach to the beta-binomial model. In the quasilikelihood approach, only assumptions regarding the mean and variance are required: $E(y_{ij}|n_{ij}) = n_{ij}\mu_i$ and $\text{Var}(y_{ij}|n_{ij}) = n_{ij}\mu_i(1 - \mu_i)[\phi(n_{ij} - 1) + 1]$. The coefficient β ’s of dose–response functions (5), (6), or (7) can be obtained by solving the quasilikelihood estimating (score) equations. The intralitter coefficient ϕ is calculated by equating with the mean of Pearson chi-square statistics. Estimation details are given by Williams [11]. The estimates of the dose–response coefficient by the quasilikelihood method are often more stable than the MLE estimates obtained by beta-binomial model.

Quantitative Risk Assessment

A fundamental goal of risk assessment is to determine safe levels of human exposure to a chemical. Such estimated levels are commonly referred to as *reference doses* (RfDs). The RfDs are presumed to cause no or negligible health risks in humans. Recently, United States Environmental Protection Agency (USEPA) [12] proposed using the benchmark dose (BMD) approach (*see Benchmark Dose Estimation*) to derive RfD for health risk assessment. The BMD refers to the dose corresponding to a prespecified benchmark response (BMR), an additional adverse response over the background response. The BMD is estimated by fitting a dose–response model to the dose–response data. Because relatively small numbers of animals are exposed to only a few dose levels and from the viewpoint of public health protection, the dose of interest is the lower confidence limit (e.g., 95%) on the BMD, denoted as BMDL. With the BMDL as a starting point-of-departure, uncertainty factors (UFs) are then employed to establish an RfD. The RfD is calculated by dividing BMDL by several UFs: $\text{RfD} = \text{BMDL}/(\text{UF}_1 \times \text{UF}_2 \times \text{UF}_3 \dots)$. The UFs can include interspecies, intraspecies, subchronic-to-chronic, lowest-observed-adverse-effect-level to no-observed-adverse-effect-level (LOAEL-to-NOAEL), etc. For example, using an UF of 1000 ($10 \times 10 \times 10$), the corresponding RfD is $\text{BMDL}/1000$.

Calculations of the MLE of BMD and BMDL are available from the USEPA Benchmark Software, which can be downloaded free of charge from the EPA home page (<http://www.epa.gov>). The MLEs of the coefficient of the dose–response models (2), (3), (5), (6), and (7) and the BMD and BMDL can be obtained using the EPA Benchmark Software. The models (2) and (3) are computed using the litter-based approach, whereas the models (5), (6), and (7) are calculated using the beta-binomial model. The model (7) is named the National Center for Toxicological Research *NCTR model* in the EPA software. Quantitative risk assessment for developmental effects *via* the BMD approach are illustrated below. The EPA Benchmark Software was used in all calculations.

Example 1 For dichotomous endpoints, the dose–response function $P(d)$ is the probability of occurrence of the adverse effect associated with the dose level d . The quantity of interest from the risk

assessment viewpoint is $\pi(d) = P(d) - P(0)$, which measures the excess risk (above the background risk) due to the added dose. For developmental effects, the BMDL corresponding to BMR value between 1 and 10% is used as a starting point-of-departure. The BMR of 10% is the default value recommended by the USEPA.

Example 1 is a study of teratogenic effects from exposure to diethylhexyl phthalate (DEHP). The experiment consisted of five dose groups of CD-1 mice with levels of 0, 44, 91, 191, and 292 mg/(kg BW) administered to pregnant females. This study showed that the DEHP exposure increased the incidence of malformation in fetuses. The complete data set was listed in Kodell *et al.* [7]. Assume the Weibull dose–response model (6) for the malformation effect. The BMD corresponding to 10% excess risk is the dose that satisfies the equation

$$0.10 = \exp(-\beta_0) - \exp(-\beta_0 - \beta_1 d_i^w) \quad (8)$$

The BMD estimate is 98 mg/(kg BW) and the BMDL estimate is 83 mg/(kg BW). If the UF of 1000 is applied, $\text{UF}_1 = 10$ for interspecies, $\text{UF}_2 = 10$ for intraspecies, and $\text{UF}_3 = 10$ for the BMR of 10% (note that the 10% excess risk may be regarded as LOAEL), then the RfD is 0.083 mg/(kg BW).

Example 2 For continuous responses, the BMR represents a change in the means response relative to the background. In the continuous response case, selection of the BMR requires judgment of what level of response should be regarded as adverse. A change in the mean of the control group equal to 1.1 standard deviation is equivalent to defining BMR of 10% for 1% background [13].

Table 1 Body weight gain in female rat from a toxicological experiment

Dose (mg/(kg BW))	<i>n</i>	Mean	Standard deviation
0	10	10.40	4.25
100	10	10.33	2.67
200	10	8.48	1.88
500	10	4.43	3.29
750	10	−4.50	2.93

Example 2 is BW changes in female rats (Table 1). These data represent typical per-litter response. The Hill equation was fit to the data. The BMR is selected

based on the 1.1 SD from the control mean (by selecting the option: BMR Type = Std. Dev and BMR = 1 in the EPA Benchmark Software). The BMD estimate is 377 mg/(kg BW) and the BMDL estimate is 275 mg/(kg BW). If the UF of 100 for interspecies and intraspecies uncertainties is applied, then the corresponding RfD is $275/100 = 2.75$ mg/kg.

Summary Comments

Developmental endpoints consist of both continuous and discrete responses data. The analysis should account for the correlations induced by the clustering effects within litters. For continuous data, the analysis of fetal responses is customarily in terms of the litter mean. However, this approach does account for differences in litter sizes. The mixed-effects model is a general parametric approach to modeling continuous outcomes. For dichotomous response, the fetal responses is summarized in terms of sum of correlated binary variables resulting in a generalized binomial distribution. The distribution for the common developmental endpoints, such as the number of malformations per litter, can be modeled by a beta binomial.

Nonclinical toxicological experiments are generally exploratory in nature with the goal of determining potential adverse effects of a chemical. The probability of detecting a statistically significant effect increases with the increased magnitude of effect and increased sample size. US regulatory guidelines generally recommend about 20 pregnant rodents and 15 nonrodent animals per dosage group. The International Conference Harmonisation guideline recommends use of 16–20 pregnant animals. However, it should be emphasized that sample size determination is preferable to arbitrary requirements for testing 16 or 20 animals as indicated in various guidelines. It is customary to specify a range of the magnitudes of the effect of interest; then an optimal sample size can be calculated to provide a reasonable power of detecting the effect. Sample-size calculations and references for various tests are provided in Desu and Raghavarao [14]. The statistical software PASS can be used for power calculation analysis and sample-size calculation (<http://www.ncss.com>).

The standard approach for assessment of developmental risks of a compound has been based on the analysis of each developmental endpoint separately.

It has been suggested that the developmental toxicity outcomes (i.e., death/resorption, malformation, growth retardation, etc.) may represent different degrees of responses to a toxic insult and occur in a dose-related manner [15]. These developmental outcomes are likely to be correlated. Therefore, a joint analysis of multiple developmental outcomes can have some advantages: it can increase the power of detecting effects if the multiple outcomes are manifestations of some common biological effects and it allows investigations of associations among the multiple outcomes if they are the results of different biological mechanisms. Various multivariate models have been developed for simultaneous analysis of multiple endpoints [16, 17].

Statistics for Environmental Toxicity

For the purpose of this article, we define “environmental toxicity” as the study of toxic hazards expressed in any environment and at any level of biological organization ranging from molecular to ecosystem level. We will use “environmental toxicology” synonymously with “environmental toxicity” here. In addition, when we mention statistical methods arising in environmental toxicity assessments, we will provide a citation to a recent environmental toxicology study where these techniques are employed. Frequently, the source of the hazard is of human origin. We include the study of adverse impacts on humans in this definition, considering humans as part of natural food chains and ecosystems. Environmental toxicity or toxicology assessments are conducted (often by statutory mandate) when evaluating the safety of materials or stressors dispersed into the environment from the agrochemical, consumer product, defense, energy, and transportation industries; and from domestic or municipal effluents and runoffs.

Where is the Environmental Impact Observed?

Environmental impacts and the statistics used to model and evaluate these impacts can be considered over multiple levels of biological organization. From the lowest level to the highest level of organization, these include molecular/genomic, tissue/organ, whole organism, population, community, ecosystem, and landscape-scale responses. Environmental toxicity research originally focused on the organismal level, but has simultaneously extended outwards in both directions to lower level responses within organisms (e.g., genomics) and higher level responses across communities of organisms and into landscape-scale responses. We consider, in turn, each level of environmental toxicological responses along with some consideration of the statistical issues that surface with each of these response levels.

Molecular/Genomic Responses

Desire to understand the mode of toxicity has led toxicologists to investigate tissue-specific, cellular, and molecular responses to hazards. In the context

of risk assessment, the investigation of molecular/genomic responses can be used to help with the identification of a compound as a potential hazard (*see* **Environmental Hazard**). Toxic effects at the molecular level include DNA modification and enzyme dysfunction. Cellular and tissue toxicity includes necrosis, cell proliferation, mutation, and cancer. The interest in greater mechanistic understanding has led to greater use of “-omics” techniques (genomics, metabonomics, proteomics, and toxicogenomics). These tools can provide data on the expression of hundreds to thousands of genes for each sample that is processed.

The statistical methods encountered here and in later sections mirror the data that are produced. For DNA modification and genotoxicity responses, toxicologists are often interested in testing for increasing trends in these endpoints. One confounder is that toxin levels that are genotoxic might also be near toxin levels that would be lethal. Thus, one problem encountered in this area is that of testing for increasing dose–response patterns with possible downturns at higher doses. The “-omics” data have been described as “large p, small n” in reflection of the situation that these methods can yield thousands of measurements on tens to hundreds of observations. Thus, toxicologists might be interested in identifying which, if any, gene(s) appears to differentially express given exposure to a toxin. This leads to statistical considerations of *multiplicity* because of testing a large number of candidate genes and descriptions of *false discovery rates* to characterize the risk that genes are incorrectly identified as differentially expressed.

Organ/Tissue Responses

Organisms are often exposed to toxins through the environment (e.g., fish or sea mammals *via* contaminated waters). The measurement of environmental toxin concentrations involves analytic chemistry to quantify the levels and statistical survey sampling to determine locations to select the samples that are evaluated. Analytic instruments have a limit of detection that may result in a number of observations occurring below this detection limit (*see* **Detection Limits**) [1]. One question of interest to environmental toxicologists is how much of this toxin is delivered to tissues that are most sensitive to it. The toxin dose (or some metabolite of the toxin) at the tissue of interest can be thought of as more closely related to

any adverse response that might be observed. Toxicokinetic models in which compartments correspond to particular organs/tissues and transitions between tissues are governed by blood flows and partition coefficients are often employed [2, 3]. The transitions between these models often involve the solution of a system of differential equations. Related kinetic models look at energy transfer in ecosystems [4].

While dichotomous responses (e.g., presence or absence of data) are commonly measured in toxicity studies, other response scales are also used. For example, the severity of tissue damage that might be associated with toxin exposure could be evaluated using a scale with levels “none”, “some”, or “severe”. This ordered severity scale might be analyzed by first dichotomizing the response scale (e.g., comparing “some” or “severe” to “none”) and applying logistic regression techniques or directly analyzing the ordinal response scale using *ordinal regression methods* [5].

Individual Organism Responses

While molecular and tissue level responses can be subtle to observe, toxic responses at the level of an individual organism are often directly observed. One common classification is to describe individual level effects as sublethal (e.g., decrements in growth, development, and reproduction) or lethal effects. The most common statistical methods encountered at this response level include anova methods and regression methods. Testing in the context of analysis of variance models might be used to identify the highest concentration group with a mean response that does not differ statistically from the mean response under control conditions, so-called no observed effect concentrations (NOECs) or the lowest concentration group with a mean response that differs statistically from the mean response observed under control conditions – lowest observed effect concentrations (LOECs). Usually, some multiple comparison procedures such as Dunnett’s procedure are used to identify these concentrations. In the case of dichotomous responses (e.g., survival) or count data (e.g., number of young produced), some transformation of the response might be employed before analyzing the data with normal-theory methods (e.g., arcsine square root for proportions and square root for counts). NOEC/LOEC calculations are still frequently used in environmental toxicology and may serve as the building blocks of other toxicity summaries such as

hazard quotients. A number of statistical critiques of these endpoints have been raised, including the restriction that these endpoints can only be one of the tested concentrations and these values will get smaller in experiments with less variability. Effective concentration estimation and benchmark concentrations (*see Benchmark Dose Estimation*) are suggested as alternatives to NOEC/LOEC calculations [6]. These alternatives involve fitting some regression model to predict the individual organism response as a function of toxin concentration. While normalizing transformations of the responses followed by multiple regression are possible, modeling responses on their observed measurement scale is more common. Generalized linear models are frequently used as a general framework for analyzing individual organism responses [7, 8]. For example, logistic regression (*see Logistic Regression*) or probit regression is usually employed for modeling dichotomous responses [9]. After fitting these models, the concentration that is associated with some specified decrement in response is estimated. A common value that is estimated by inverting these regression models is the concentration associated with 50% mortality, the median lethal concentration or LC₅₀. When analyzing nonlethal responses, the impact level is often described as the effective concentration associated with p% impact or EC_p. The LC_p and EC_p can be considered potency estimates that are derived from inverting a regression model to estimate the concentration associated with some specified impact level. In environmental risk assessment, the potential risk of adverse response at a site might be investigated by constructing a hazard quotient = (environmental exposure concentration)/(toxicity reference value) where the toxicity reference value is a LC_p, EC_p, NOEC, or LOEC [10]. Hazard quotients are deterministic values that have been used to portray potential risk. These values are not actual estimates of risk and do not account for uncertainties in the endpoint estimates. Probabilistic risk assessments use probability distributions of potency estimates and exposure scenarios, in combination with Monte Carlo simulation to derive quantitative estimates of risk along with estimates of variability and uncertainty in these values [11, 12].

Population Responses

Population level effects can be summarized in a variety of terms including mean changes in various

population level traits. A population can be conceptualized as a collection of individuals at various life stages and/or ages. A population can be altered by a number of factors including immigration of new individuals, reduction in reproduction rates, and mortality of early age/stage individuals. The impact of an environmental toxin can be observed in a variety of population level changes. For example, a toxin might reduce fecundity or it might alter the transition of organisms from one life stage to another (e.g., juvenile to adult) or, most dramatically, it might increase the probability of species extinction. Population level studies might investigate life history [13] as well as population growth and recovery [14]. Statistical models for analyzing population impact range from logistic methods for survival and breeding condition to investigating systems of age-structure/life stage stages using Leslie matrices.

Community and Ecosystem Responses

Better appreciation of ecological issues has pushed environmental toxicology in the direction of deeper understanding of species interactions at the community and ecosystem level. The effects of these levels can be evaluated along a variety of different dimensions. What species are most sensitive to a toxin? Does a contaminant biomagnify across trophic levels, i.e., does a toxin increase in predators higher on the food chain because of consuming a persistent toxin in prey? Can a species be determined that would be a sentinel for evaluating whether a hazard has been used? Does exposure to a toxin alter the diversity, richness, or structure of an ecological community? How can distributions of species sensitivity to a toxin be used to set an exposure level that would be protective of most species in an ecosystem? How do environmental pollutants affect biogeochemical cycles and what impact does this have on populations or communities?

Community metrics provide a means of evaluating complex environmental systems. For example, the index of biotic integrity (IBI) is a scale that uses the presence or absence of certain key fish species to “grade” the quality of a stream [15, 16]. The IBI values are then grouped into categories of impact using stream systems with known impact to help set quality categories. This concept of community indexes of biotic integrity has been extended to many other assemblages, including invertebrates [17], plankton [18, 19], birds [20], and ecosystems

[21, 22]. Statistical methods to formalize this classification might include some cluster analytic methods [17]. Another important community response idea that is often used in environmental toxicology, especially as it relates to environmental risk assessment, is the species-sensitivity distribution, which is the cumulative distribution function (CDF) for endpoints derived from concentration–response studies (e.g., EC_p and NOEC). The fifth percentile of this distribution, the HC₅, is frequently estimated and used to represent a concentration that would materially impact 5% of the species while not seriously impacting the other 95% [23, 24]. The estimation of the confidence intervals associated with HC₅ has been a statistical problem addressed by a number of techniques including bootstrapping [25].

Landscape-Scale Responses

The display and analysis of the impact of environmental toxins across a spatial region has led to an increase in the use of spatial statistical methods [26] for modeling and prediction and geographic information systems (GIS) [27, 28] for display. Interestingly, these data share some of the features of the “-omics” data. In other words, a large number of variables are measured on a small number of observations. Finally, Bayesian statistical methods (*see Bayesian Statistics in Quantitative Risk Assessment*) are becoming more commonly encountered in the field of environmental toxicity including assessments of uncertainty and variability in a hierarchical model for a bioaccumulation model [29] and examining latent variables and spatio-temporal trends [30].

Other Issues

There are a number of statistical considerations that are encountered at a number of the ecological measurement scales. A form of censoring (*see Censoring*) occurs when responses are not observed by the scheduled end of observation in a study. This situation leads to the use of survival analytic methods [31]. The analysis of environmental exposures to mixtures of toxins is an area of active investigation [32]. Questions of dose-additivity or response-additivity can be used to determine toxicity units or toxic-equivalence factors that might be part of an environmental risk assessment.

Stochastic Control for Insurance Companies

Running a company means to take decisions all the time. One tries to take the decision in an optimal way. Thus, for taking a decision, the management has to solve an optimization problem. Of course, often the optimization problem (*see Asset–Liability Management for Life Insurers; Longevity Risk and Life Annuities; Multiattribute Modeling*) is not explicitly given. The decisions are therefore taken intuitively. However, to get a feeling about which decision should be taken, or to understand how the economy is working, economists, engineers, and mathematicians have developed tools to find or to approximate optimal decisions.

In an insurance company, economic quantities are not the only important factors. An actuary has to take the policy holders' interests into consideration. Thus an actuary has to optimize two contrary positions at the same time: from the point of view of a policy holder, or alternatively the supervisor (like the problems in the sections titled “Optimal Reinsurance” and “Optimal New Business”), from the point of view of a share holder (like in section “Optimal Dividends”), or from some mix of the interests of policy holders and managers (like in section titled “Control of a Pension Fund”).

In this article, we give some examples to illustrate how dynamic optimization problems (*see Role of Alternative Assets in Portfolio Construction; Reliability of Large Systems*) can be solved by stochastic methods. Because we want to keep it simple, we use simple (generic) models and consider simple value functions. For these optimization problems, it will not be difficult to determine the solutions, even though, typically, the solutions have to be obtained numerically. We skip many details. More information and further references can be found in Schmidli [1].

The Basic Model

We start by considering two possibilities to model the surplus of some insurance portfolio. The *classical Cramér–Lundberg model* (*see Large Insurance*

Losses Distributions; Ruin Probabilities: Computational Aspects) in nonlife insurance is

$$X_t = x + ct - \sum_{k=1}^{N_t} Y_k \quad (1)$$

x is the initial capital, i.e., the capital at risk for the considered portfolio of insurance contracts. The premium income is linear with rate c . This is an idealization to make the model tractable. The claim number process is a Poisson process with claim arrival intensity λ (the mean number of claims in a unit interval). The claim sizes $\{Y_k\}$ are independent and identically distributed (i.i.d.) with distribution function $G(y)$ and independent of the claim arrival process $\{N_t\}$. We assume that $G(0) = 0$, i.e., all claims are positive.

Optimal Reinsurance

A main tool for an insurer to decrease his risk is to buy reinsurance (*see Credit Risk Models; Dynamic Financial Analysis; Securitization/Life*). This reduces the capital required by the supervisor. The insurer would then want to know how much reinsurance should be purchased. A popular form of reinsurance is proportional reinsurance. For this form, a retention level $b \in [0, 1]$ is chosen. For a claim Y , the insurer then covers bY ; the rest is covered by the reinsurer. We now allow the insurer to change the retention level continuously. This yields the surplus process (*see Insurance Pricing/Nonlife*) $X_t^b = x + \int_0^t c(b_s) ds - \sum_{k=1}^{N_t} b_{t_k} Y_k$. Here, $b_t \in [0, 1]$ is the retention level chosen at time t , $c(b)$ is the premium rate net the premium rate for reinsurance, and b_{t-} is the retention level (*see Individual Risk Models; Solvency*) chosen immediately prior to t . We suppose that $c(b)$ is strictly increasing in b (more reinsurance costs more), $c(1) = c$ (no reinsurance does not cost anything), and $c(0) < 0$ (full reinsurance is more expensive than first insurance). We define the time of ruin by $\tau^b = \inf\{t : X_t^b < 0\}$ ($\inf \emptyset = \infty$) and the survival probability (*see Default Correlation; Lifetime Models and Risk Assessment*) $\delta^b(x) = \mathbb{P}[\tau^b = \infty]$. The survival probability is a classical measure for the risk and it is also used in the Solvency II agreement (*see Credit Risk Models; Nonlife Insurance Markets*). The goal is to maximize the survival probability. We therefore consider the value function is $\delta(x) = \sup_b \delta^b(x)$, where the maximum

is taken over all strategies $\{b_t\}$, using only the information available until time t .

The problem cannot be solved directly. The following (technical) considerations illustrate how mathematicians can find an equation that the value function should fulfill (see **Multiattribute Value Functions**). Suppose, for the moment, that the strategy $b_t = b$ is constant in a small time interval $(0, h)$ ($h > 0$). After time $T_1 \wedge h = \min\{T_1, h\}$, we follow the optimal strategy, which, we suppose exists for the derivation of equation (5). With probability $e^{-\lambda h}$, there is no claim in $(0, h)$. In this case, the capital at time h is $x + c(b)h$. A claim in $(0, h)$ happens with density $\lambda e^{-\lambda t}$. If a claim happens at time t , then the capital at time t becomes $x + c(b)t - bY_1$. Ruin occurs at time T_1 , if $Y_1 > (x + c(b)t)/b$. Thus we obtain the equation

$$\begin{aligned} \delta(x) &\geq \delta^b(x) = e^{-\lambda h} \delta(x + c(b)h) + \int_0^h \lambda e^{-\lambda t} \\ &\quad \times \int_0^{(x+c(b)t)/b} \delta(x + c(b)t - by) dG(y) dt \end{aligned} \quad (2)$$

Rearranging the terms and dividing by h we obtain

$$\begin{aligned} &\frac{\delta(x + c(b)h) - \delta(x)}{h} - \frac{1 - e^{-\lambda h}}{h} \\ &\quad \times \delta(x + c(b)h) + \frac{1}{h} \int_0^h \lambda e^{-\lambda t} \int_0^{(x+c(b)t)/b} \\ &\quad \times \delta(x + c(b)t - by) dG(y) dt \leq 0 \end{aligned} \quad (3)$$

Supposing that $\delta(x)$ is differentiable, we obtain the limit letting $h \downarrow 0$

$$c(b)\delta'(x) + \lambda \left[\int_0^{x/b} \delta(x - by) dG(y) - \delta(x) \right] \leq 0 \quad (4)$$

This has to hold for all $b \in [0, 1]$. Thus the equation also has to hold if we take the maximum on the left-hand side of equation (4). This motivates the *Hamilton–Jacobi–Bellman equation* (see **Role of Alternative Assets in Portfolio Construction; Reliability Optimization**)

$$\begin{aligned} &\sup_{b \in [0, 1]} c(b)\delta'(x) + \lambda \left[\int_0^{x/b} \delta(x - by) dG(y) - \delta(x) \right] \\ &= 0 \end{aligned} \quad (5)$$

A discussion on why equality should hold instead of the inequality can be found in [1].

Let $b(x)$ be an argument maximizing the left-hand side of equation (5). Because one can argue that $\delta(x)$ is a strictly increasing function, we find that $c(b(x)) > 0$. Let $B = \{b \in [0, 1] : c(b) > 0\}$. For $b \in B$ we have $\delta'(x) \leq \lambda \{c(b)\}^{-1} [\delta(x) - \int_0^{x/b} \delta(x - by) dG(y)]$. Because for $b = b(x)$ the equality has to hold, we get the alternative form of the Hamilton–Jacobi–Bellman equation

$$\delta'(x) = \inf_{b \in B} \lambda \frac{\delta(x) - \int_0^{x/b} \delta(x - by) dG(y)}{c(b)} \quad (6)$$

We can interpret the right-hand side by choosing the $b(x)$ to make the derivative of $\delta(x)$ minimal. This makes sense because we have the boundary condition $\delta(\infty) = 1$, hence the minimal derivative makes $\delta(x)$ maximal.

The derivation of equations (5) and (6) was heuristic. Therefore, one has first to prove a so called *verification theorem*. If we assume that there is a solution $f(x)$ to equation (5) or equation (6) with $f(0) > 0$, then $f(x)$ is strictly increasing and bounded. Moreover, $f(x) = f(\infty)\delta(x)$, and the strategy $b_t = b(X_t)$ is optimal, where $b(x)$ is an argument where the sup (inf) is taken in equations (5), (6), respectively. Thus if a solution to the Hamilton–Jacobi–Bellman equation exists, then we have obtained the correct value function.

Because for any solution $f(x)$ to equation (5), $\alpha f(x)$ is also a solution for any constant $\alpha > 0$, we can start with $f(0) = 1$ for a numerical solution. It follows then that $\delta(x) = f(x)/f(\infty)$. It remains to show that in fact $\delta(x)$ solves equation (5). Because of the verification theorem, it is enough to show that there is a solution to equation (5). For this purpose, we start with $f_0(x) = \delta^1(x)/\delta^1(0)$, where $\delta^1(x)$ is the survival probability if no reinsurance is taken. Then we let recursively $f'_{n+1}(x) = \inf_{b \in B} \lambda \{c(b)\}^{-1} [f_n(x) - \int_0^{x/b} f_n(x - by) dG(y)]$, and $f_{n+1}(x) = 1 + \int_0^x f'_{n+1}(z) dz$. It turns out that $f'_n(x)$ is decreasing in n , and therefore $f_n(x)$ converges to some function $f(x)$ solving equation (6). Thus we have shown that there is a (unique) solution $f(x)$ to equation (6) with $f(0) = 1$.

Example 1 Suppose now that the claim sizes are mixed, exponentially distributed $G(y) = 1 -$

Figure 1 $\delta(x)$ and $\delta^1(x)$ (a) and optimal strategy (b) for mixed exponentially distributed claim sizes

$\frac{1}{3}e^{-0.5y} - \frac{2}{3}e^{-2x}$. One could interpret this distribution function as two sorts of claims: one with mean value 2 appearing with probability $1/3$, the other one with mean value $1/2$, appearing with probability $2/3$. The mean value of the claim sizes is one. We choose $\lambda = 1$ (one claim per time unit) and $c(b) = 1.7b - 0.2$. That is, the premium is $c(1) = c = 1.5$ i.e., the insurer asks for a safety loading of 50% of the net premium. The reinsurer uses a safety loading of 70%. If the process is not controlled, the survival probability is $\delta^1(x) = 1 - 0.606423e^{-0.204667x} - 0.0602437e^{-1.62866x}$. This can be calculated by standard methods. Solving equation (5) gives the optimal survival function $\delta(x)$ and the optimal strategy $b(x)$. Figure 1 shows the uncontrolled survival probability $\delta^1(x)$ and the optimal survival probability $\delta(x)$, as well as the optimal strategy. For small initial capital, one chooses no reinsurance. To buy reinsurance does not strongly reduce the ruin probability. Therefore one wants to get away from zero as quickly as possible. Around $x = 3.3$, one starts to buy reinsurance. The strategy then has a jump.

It can be shown that $\psi(x) = 1 - \delta(x) \sim \xi e^{-Rx}$ as $x \rightarrow \infty$ for some $\xi > 0$. The exponent R is the maximal adjustment coefficient. For our model, we obtain $R = 0.291223$, which is about 50% larger than the adjustment coefficient in the noncontrolled case where $R^1 = 0.204667$. The strategy $b(x)$ converges as $x \rightarrow \infty$ to $b^R = 0.493525$, the retention level for which the maximal adjustment coefficient R is attained. The reduction of the ruin probability is also present for the *value at risk* (see **Credit Migration Matrices; Default Risk**). This is the capital required by the Solvency II rules for insurance companies. $\text{VaR}_{0.05}$ becomes approximately 12.2 for the noncontrolled surplus and approximately 8.5 for

the optimal control. The capital needed for not controlling is therefore approximately 50% larger than for the optimal control.

Optimal New Business

Economists often try to lower the risk by diversification. That is, capital invested is split to independent assets. For an insurer, there is the possibility to participate in some risk exchange. That is, it is possible to buy part of a portfolio from another insurer. We call this risk “new business”. The new business should then cover risks in some area other than the insurer’s original portfolio for the risk to become independent. We simplify the situation in such a way that the insurer is not allowed to sell his original portfolio and can buy or sell part of the new business at any time.

This problem was first treated by Hipp and Takar [2]. The following results can be found in their paper. Suppose the insurer, with the surplus process $\{X_t\}$ modeled by equation (1), has the possibility to buy or sell parts of another surplus process $\{Z_t\}$ with Poisson parameter ℓ , claim size distribution $F(y)$, and premium rate ζ . The net profit condition $\zeta > \ell \int_0^\infty (1 - F(y)) dy$ is fulfilled. At time t , the insurer has the fraction $b_t \in [0, 1]$ of the process $\{Z_t\}$ in his portfolio. Then the surplus of the insurer is $X_t^b := X_t + \int_0^t b_s \zeta - dZ_s$. The goal here is also to minimize the ruin probability. The corresponding Hamilton–Jacobi–Bellman equation is

$$\sup_{b \in [0, 1]} (c + b\zeta)\delta'(x) + \lambda \left[\int_0^x \delta(x - y) dG(y) - \delta(x) \right] + \ell \left[\int_0^{x/b} \delta(x - by) dF(y) - \delta(x) \right] = 0 \quad (7)$$

The alternative form of equation (7) is

$$\delta'(x) = \inf_{b \in [0, 1]} \frac{\lambda \left[\delta(x) - \int_0^x \delta(x-y) dG(y) \right] + \ell \left[\delta(x) - \int_0^{x/b} \delta(x-by) dF(y) \right]}{c + b\zeta} \quad (8)$$

Similarly, for optimal reinsurance, one can prove that there is a unique solution $\delta(x)$ to equations (7) and (8), and this solution is the value function. The strategy $b_t = b(X_t)$ is optimal, where $b(x)$ is an argument at which the supremum on the left-hand side of equation (7) (or infimum in equation (8)) is taken. In the paper by Hipp and Taksar [2], the problem also considered is one in which the process b_t is only allowed to be increasing, i.e., the new risk can only be purchased, but not be sold.

Optimal Dividends

An economist would usually measure the value of a company by the value of the future dividend payments. Thus de Finetti [3] proposed to allow the insurer to pay out a dividend. The postdividend process is $X_t^D = X_t - D_t$, where $\{D_t\}$ is an increasing process with $D_{0-} = 0$. The value of a dividend strategy is $V^D(x) = \mathbb{E}[D_0 + \int_0^{\tau^D} e^{-\delta t} dD_t]$, where $\delta > 0$ is a discount factor, meaning that dividends today are preferred to dividends tomorrow. The time $\tau^D = \inf\{t > 0 : X_t^D < 0\}$ is the time of ruin. At this time, new capital has to be raised to proceed with the business. A share holder is then interested in getting the maximal value of the dividends.

The value function is $V(x) = \sup_D V^D(x)$, where the maximum is taken over all dividend strategies on the basis of the information available, such that $\Delta D_\tau = D_\tau - D_{\tau-} = 0$ (no dividends at ruin).

We start with the classical model (1). There are areas where dividends are paid out and areas where no dividend is paid out. Thus we can expect areas where $\Delta D_t > 0$ and areas where $dD_t = 0$. If $X_t = z$ is such that there is $\varepsilon > 0$ such that no dividends are paid out on $(z - \varepsilon, z)$ and dividends are paid out in $(z, z + \varepsilon)$, then one has to pay out the incoming premiums, i.e., $dD_t = c dt$. On an area where dividends are paid out we obviously have $V'(x) = 1$. On the area where no dividends are paid out one has $V'(x) \geq 1$ because otherwise it would be preferable to pay out the dividends immediately. On

an interval on which no dividends are paid out, the function $V(x)$ has to solve the equation $cV'(x) + \lambda \int_0^x V(x-y) dG(y) - (\lambda + \delta)V(x) = 0$. This can be verified in way similar to inequality equation (4). This leads to the Hamilton–Jacobi–Bellman equation

$$\max \left\{ cV'(x) + \lambda \int_0^x V(x-y) dG(y) - (\lambda + \delta)V(x), 1 - V'(x) \right\} = 0 \quad (9)$$

The proof that $V(x)$ really solves equation (9) is very technical. For details see [1].

The optimal strategy is constructed in the following way. If $V'(x) > 1$, then no dividend is paid out. On interior points where $V'(x) = 1$, the minimal amount is paid out such that a point is reached where the incoming premiums are paid out. On the lower bound of points where dividends are paid out, the incoming premium is paid out as a dividend. That the optimal dividend strategy is of the form described above was first proved by Gerber [4].

Control of a Pension Fund

Consider a pension fund (*see Actuary; Comonotonicity*) and model the outgo for benefits by a diffusion approximation $bt + \sigma_B W_t^B$. One has the possibility to invest into a risky asset and a riskless asset, modeled as a Black–Scholes model (*see Default Risk; Statistical Arbitrage*) given by the (stochastic) differential equations $dZ_t = mZ_t dt + \sigma_1 dW_t^1$ and $dZ_t^0 = \delta Z_t^0 dt$, respectively. The Brownian motions $\{W_t^1\}$ and $\{W_t^B\}$ are supposed to be independent. The pension fund can decide on the proportion θ_t invested into the risky asset at time t and the contribution rate c_t . Then the fund size is described by the stochastic differential equation

$$dX_t^{\theta, c} = [(1 - \theta_t)\delta + m\theta_t]X_t^{\theta, c} dt + \sigma_1 \theta_t X_t^{\theta, c} dW_t^1 + (c_t - b) dt - \sigma_B dW_t^B \quad (10)$$

The fund should keep its size and the contribution rate close to some predefined values $\hat{x}$ and $\hat{c}$, respectively. One therefore chooses a loss function $L(c, x) = (c - \hat{c})^2 + 2\rho(c - \hat{c})(x - \hat{x}) + (k + \rho^2)(x - \hat{x})^2$. This means one punishes deviations from the target values. The parameter ρ allows to skew the punishment, that is, one defines preferences about which directions the deviations should go.

The loss of a strategy $\{\theta_t, c_t\}$ is $V^{\theta,c}(x) = \mathbb{E}[\int_0^\infty e^{-\beta t} L(c_t, X_t^{\theta,c}) dt \mid X_0^{\theta,c} = x]$. The parameter $\beta > 0$ gives some preferences. If β is close to zero, then deviations in the moderate future are punished as well. If β is large, then one wants to be close to the target values now and does not mind much about the future.

The value function is now the minimal expected loss $V(x) = \inf_{\theta,c} V^{\theta,c}(x)$. The corresponding Hamilton–Jacobi–Bellman equation becomes

$$\inf_{\theta,c} L(c, x) + \frac{1}{2}(\sigma_1^2 \theta^2 x^2 + \sigma_B^2) V''(x) + \{(1 - \theta)\delta + m\theta\}x + c - b\} V'(x) - \beta V(x) = 0 \quad (11)$$

The left-hand side is quadratic in c and θ . Thus we have to solve

$$\begin{aligned} & -\frac{1}{4} V'^2(x) + k(x - \hat{x})^2 - \frac{(m - \delta)^2 V'^2(x)}{2\sigma_1^2 V''(x)} \\ & + \frac{1}{2} \sigma_B^2 V''(x) + (\delta x + \hat{c} - \rho(x - \hat{x}) - b) V'(x) \\ & - \beta V(x) = 0 \end{aligned} \quad (12)$$

Trying a solution of the form $V(x) = Ax^2 + Bx + C$ yields the solution

$$\begin{aligned} A &= -\frac{(m - \delta)^2}{2\sigma_1^2} + (\delta - \rho) - \frac{1}{2}\beta \\ &+ \sqrt{\left(-\frac{(m - \delta)^2}{2\sigma_1^2} + (\delta - \rho) - \frac{1}{2}\beta\right)^2 + k} \\ B &= \frac{2[(\hat{c} + \rho\hat{x} - b)A - k\hat{x}]}{A + (m - \delta)^2\sigma_1^{-2} + \beta + \rho - \delta} \\ C &= \beta^{-1} \left[-\frac{B^2}{4} + k\hat{x}^2 - \frac{(m - \delta)^2 B^2}{4A\sigma_1^2} \right. \\ & \left. + \sigma_B^2 A + (\hat{c} + \rho\hat{x} - b)B \right] \end{aligned} \quad (13)$$

Note that the other solution for A is strictly negative and therefore is not the desired solution because we need a convex solution.

It is proved in Cairns [5], see also [1], that the value function really is $V(x) = Ax^2 + Bx + C$ with A, B, C given above. The optimal strategy is of feedback form $\{(\theta_t, c_t)\} = \{(\theta(X_t), c(X_t))\}$ with

$$\begin{aligned} \theta(x) &= -\frac{(m - \delta)(Ax + B/2)}{\sigma_1^2 Ax}, \\ c(x) &= \hat{c} - \rho(x - \hat{x}) - Ax - B/2 \end{aligned} \quad (14)$$

Note that we take a short position (see **Credit Risk Models**) in the risky asset if the reserve lies above $-B/(2A)$. In some sense, we “destroy” wealth if our reserve is too large. This is because the loss function punishes a position above the target value in the same way as a position below. One therefore should choose a more reasonable loss function than quadratic loss.

HANSPETER SCHMIDLI

Stratospheric Ozone Depletion

Stratospheric ozone (O_3) shields the surface of the Earth from solar short-wave ultraviolet B (UVB) radiation. A model of the photochemical process responsible for the formation and destruction of ozone was first proposed by Chapman [1]. Chapman's model involved rapid recycling between oxygen and ozone. This model has since been extended and it is now understood that stratospheric ozone is destroyed not only by oxygen but also by other chemical species. In the 1970s, it was recognized that chlorine could catalyze ozone destruction and, in 1974, Mario Molina and Sherwood Rowland identified man-made chlorofluorocarbons (CFCs) as the main source of ozone-destroying chlorine in the stratosphere [2]. For this work, Molina and Rowland shared the 1995 Nobel prize in Chemistry with Paul Crutzen. Excellent surveys of the processes governing the concentration and distribution of ozone in the stratosphere can be found in Solomon [3] and Staehelin *et al.* [4].

The use of CFCs in refrigerators, aerosol sprays, and cleaning solvents began in the 1930s and, with increased use, their atmospheric concentrations grew rapidly. The discovery of their role in the destruction of stratospheric ozone caused considerable concern about these increasing concentrations. This concern revolved around the potential risks of increased levels of UVB radiation to human health. These risks include elevated rates of skin cancer, eye disease, and immune system suppression [5]. Increased UVB radiation also poses a potential ecological risk owing to its effects on animal health and plant growth.

Concern over ozone depletion led to calls in the 1980s for an international agreement to control the production of CFCs and other ozone-depleting compounds. A central question in the debate over such an agreement concerned the magnitude of the risks posed by ozone depletion. Although the basic chemistry of ozone depletion had been well understood since the work of Molina, Rowland, and others in the 1970s, to assess the risks of ozone depletion to human health and ecosystems, it was necessary to know how the actual concentration of stratospheric ozone had varied – and would likely vary in the future – over particular regions of the Earth's surface. The spatial

and temporal distribution of ozone in the stratosphere is affected by a number of factors, including solar variability, volcanic activity and atmospheric chemistry, temperature, and circulation. A striking example of this is the formation of so-called ozone holes in the spring over the North and South Poles. These dramatic, but temporary, reductions in ozone concentration are associated with atmospheric anomalies called *polar vortices*. The formation of polar vortices has substantial local effects on ozone dynamics. In particular, when a polar vortex forms, extremely cold polar air is essentially isolated from atmospheric circulation. The cold temperatures promote the process of ozone destruction and the isolation prevents relatively ozone-rich air from midlatitudes from flooding in. Although several studies have shown that the depth and spatial extent of the polar ozone holes have increased over time, these phenomena are restricted to polar regions.

The understanding of the role of these and other (possibly unknown) factors in determining the details of ozone concentration was felt by many to be insufficiently developed to serve as the sole basis of a quantitative risk assessment. As a result, statistical analyses of ozone concentrations came to play a central role in the scientific discussion.

Surface measurements of total column ozone were first made in the 1920s using an instrument called the *Dobson spectrophotometer*. Briefly, the Dobson ozone measurement is based on the ratio of intensities of incoming solar radiation at two UV wavelengths, one of which is strongly absorbed by ozone while the other is not. The measurement is calibrated from knowledge of these intensities at the top of the atmosphere. The longest record of Dobson measurements, which began in 1926, is for Arosa, Switzerland. However, it was not until the International Geophysical Year of 1957 that a broad network of Dobson stations was established. Solow [6] reviewed two analyses of the Dobson data by Reinsel and Tiao [7] and Bloomfield *et al.* [8] aimed at estimating a global trend. Although differing in a number of ways, both analyses were based on statistical models incorporating a regional component, a seasonal component, and a secular temporal trend. In addition, both models made allowance for temporal correlation in unmodeled ozone variations. The original papers should be consulted for model details. Reinsel and Tiao represented the trend as constant up to 1970, followed by a linear trend. They found no significant depletion

over the period 1970–1983. This result remained unchanged when a measure of solar variability was included in the analysis. Bloomfield *et al.* assumed that the trend was proportional to an ozone depletion curve based on a photochemical model and also allowed for a solar effect and the effect of atmospheric nuclear tests. The best-fitting depletion curve was around 10% of that predicted by the photochemical model. In overall terms, these two analyses found little evidence of global ozone depletion over the observation period. Other analyses of global total column ozone found similar results.

Dobson measurements of total column ozone can be converted into estimates of the vertical profile of ozone concentration using the Umkehr method. The Umkehr method is based on a division of the atmosphere into separate layers. The distribution of ozone across these layers is estimated from the variation in the Dobson measurement as the sun subtends an angle of 60–90° near dawn and dusk. Because photochemical models suggest that ozone depletion should be greatest in the upper atmosphere, Reinsel and Tiao repeated their analysis for the upper five Umkehr layers. In doing so, they had to deal with a large number of missing observations. The extended analysis found significant ozone depletion in the upper three Umkehr layers.

In addition to the ground-based Dobson data, satellite measurements of ozone have been available since the late 1970s. The longest record, which began in 1978, is for the total ozone mapping spectrometer (TOMS) aboard the NIMBUS 7 satellite. This instrument operates on the same general spectrometric principles as the Dobson instrument, but uses reflected, rather than incident, solar radiation. An advantage of the TOMS data over the ground-based data is its global coverage. Niu and Tiao [9] used the TOMS data to investigate trends at different latitudes in total column ozone over the period 1978–1990. A central part in their analysis was the incorporation of a spatial–temporal autocorrelation (STAR) model into the error process (*see Spatial Risk Assessment*). Again, the original paper should be consulted for model details. Assuming linear trends, Niu and Tiao found rates of depletion increasing asymmetrically with latitude from essentially 0° at the equator to 4% per decade at 65°N and 10% per decade at 65°S.

By the mid-1980s, the risks of ozone depletion were felt to be substantial enough that an international agreement called the *Montreal Protocol* was

signed in 1987 to limit the production of CFCs and other ozone-depleting compounds. The Montreal Protocol, which was amended in 1990 and 1992, has successfully reduced CFC emissions. As the lifetime of CFCs in the atmosphere is on the order of 50–100 years, the full effect of the Montreal Protocol will not be felt for decades. Efforts have been made, however, to identify an effect on ozone concentration. Newchurch *et al.* [10] analyzed data from two satellite experiments – the Stratospheric Aerosol and Gas Experiment (SAGE) and the Halogen Occultation Experiment (HALOE) – over the period 1979–2000 to address this issue. Briefly, the analysis began by fitting a statistical model similar to those described above to data over the period 1979–1996. An attempt was made in this model to account for the effect of solar variability and the quasi-biennial oscillation (QBO), an atmospheric oscillation of period ~2.5 years. Also, ozone observations contaminated by volcanic eruptions and other aerosol effects were omitted from the analysis. In the second part of the analysis, the cumulative sums (CUSUMs) of deviations from the fitted model for the out-of-sample period 1997–2000 were used to detect a decrease in the rate of ozone depletion. The results suggest that such a slowdown had indeed occurred. Future statistical work in this area would benefit from going beyond relatively simple model specifications – involving, for example, linear trends – to incorporating the output of physical models as in Bloomfield *et al.* [8]. A more recent example of this kind of work is described in Guillas *et al.* [11], in which a physical model of chemical transport is used to assess ozone recovery following the implementation of the Montreal Protocol.

Stress Screening

Stress screening (*see Credit Migration Matrices; Extreme Values in Reliability; Reliability Integrated Engineering Using Physics of Failure*) is a combined stress and functional test applied to products prior to dispatch to prevent the delivery of parts with latent defects that may cause failure at some time during use. Manufacturers use it as a final check process to limit the risk of failure within the guaranteed life and avoid the resulting consequences. Stress screening is very rarely used for mass produced items and is only applied to medium- and low-volume products in particular circumstances. It is sometimes employed when product manufacture involves materials or processes that are difficult to fully control and are likely to include or create latent defects. It is more often used for high-quality, low-volume, complex products, where the consequences of service failure are severe. The consequences may be financial owing to contractual penalties or warranty or may have individual or more general public safety issues. A very simple example of stress screening, although never so-called, is the proof (over pressure) test of a pressure vessel. The stress applied during the screening is usually environmental, e.g., temperature or vibration, and hence its alternative name of environmental stress screening (ESS) (*see Accelerated Life Testing*). The test condition usually comprises more than one stress and can also include product-related loads, e.g., voltage, in an electrical product. Traditionally, the stress applied is restricted to specification limits but, more recently, it has become accepted to use greater stresses in order to increase screen effectiveness. The screening regime is related to a stress testing reliability enhancement process at design stage that increases applied stress to the point of product failure. This determines the margin over the specification limit built into the design and the results can be used to set safe screening levels outside the specification.

One should never use stress screening as a replacement for manufacturing process control or to enable the fielding of poorly designed products. Ensuring that a product is fit for purpose by development testing at the design stage and controlling the materials and processes used in manufacture are much more cost-effective methods of minimizing service failures.

Stress screening is testing designed to overstress latent manufacturing defects with a potential to cause field failure so that they can be detected and not delivered. Stress screening is useful in identifying batch-related and systematic manufacturing problems so that corrective action can be undertaken avoiding product recalls and is a process that enables a continuous improvement environment.

Typical Applications

Applications are typified by low-volume products with manual intervention in final assembly and where the consequences of service failure are severe. In the aviation industry, particularly for electromechanical and electronic systems, stress screening is used extensively and often mandated by the customer. For example, despite the redundancy embedded in the design of a full authority digital engine control (FADEC) controlling a large civil airplane engine, stress screening is used to reduce the risk of service failure and engine run down. The difficulty we experience is in specifying the screening strategy and stress levels so that maximum benefit follows, i.e., 100% detection of defective products with no weakening of good products.

Developing a Stress Screening Regime

There has been a recent tendency, driven by proactive equipment suppliers, to try and impose a standard basic screening regime with variation in stress level alone. This is ill-conceived as every product and application should be considered independently. The key factors to consider in determining the need to screen and selecting the applied stresses are product construction and application environment.

The structure of the product is important as some sublevel screening may be desirable, particularly if appropriate stress cannot be easily applied to individual parts when the product is fully assembled. For example, a process flow involving the screening of individual devices and printed circuit board assemblies as well as the completed product is often used for high-reliability electronic products.

Most product failures, even in electronics, are thermomechanical in nature and an appreciation of the field environmental stresses likely to promote latent defects to failure is essential. Transport and storage conditions should also be considered, as for

benign applications they may be the worst conditions experienced. However, the best guide is provided by an analysis of the field failures of a similar product. A Pareto analysis (*see Large Insurance Losses Distributions; Ruin Probabilities: Computational Aspects*) of the defects that escape and cause field failure indicates what the screening must be designed to identify.

The use of stress levels beyond specified limits raises the possibility of the screen causing damage to products released to service; therefore, we must design the screening very carefully. The following inputs should be considered when setting stress levels:

1. Marginal conditions indicated by simulation of product performance under the expected extremes of environmental stress and product loads.
2. Formal design and process failure modes effects and corrective action (FMECA) studies.
3. Failure concerns elicited from design and manufacturing engineers and operators as they often understand the product and its potential weaknesses better than anyone.

The ideal level of stress can be better appreciated by considering the diagram (see Figure 1) where *specification limit* is the extremes of the environment specified by the customer or expected, given the application. *Design limit* is the limit within which the device has been theoretically designed to operate, giving some margin over the worst expected

conditions. *Operating limit* is the functional limit, characterized by soft failure, i.e., beyond this functionality is lost but resumes after removal of stress. *Destruct limit* is the point at which hard failure occurs, i.e., functionality does not resume after removal of stress. Ideally, the screening stress range should be as indicated but this is a theoretical diagram and the various limits are seldom known for certain and can vary with product or component batch. It is also always preferable to monitor function throughout the test as failure may occur at only certain parts of the stress regime.

The commonly used stresses are temperature, rapid change of temperature, vibration, mechanical shock, mechanical stress, voltage, and rapid on-off cycles. The means of applying stress will be product dependent and may be by operation outside normal limits. Stresses applied in combination can also be more effective, e.g., vibration at elevated or low temperatures is often more damaging as the stiffness of different materials can change significantly with temperature.

Screening Equipment

We have emphasized the need to treat every product on its own merits but the screening conditions used often involve temperature and vibration. Conventional temperature and vibration test chambers can be used, but equipment is available specifically developed for product screening and the allied step-stress development testing. The equipment manufacturers have introduced the names highly accelerated life testing (HALT) (*see Hazard and Hazard Ratio*) for such reliability testing at design and highly accelerated stress screen (HASS) (*see Product Risk Management: Testing and Warranties*) for accelerated stress screening [1]. These equipment employ rapid thermal cycling and six degrees of freedom, repetitive shock testing, akin to a multidirectional random vibration.

Screen Validation and Feedback

Even if stress levels are maintained within the operating limit, there is still a danger that significant life may be taken out of the product. Analysis using physics of failure life prediction under the applied stresses can be used to indicate if there is any reason for concern. The promoters of the HASS technique

Figure 1 Schematic of stress levels in stress screening

recommend a validation test, where they submit a sample product to 20 times the proposed screen. If still working they conclude that the screen, at worst, will not take more than 5% of the life out of the product.

Whatever screening process is used, to be really effective it must be accompanied by a thorough analysis of both screening and field failures. This continuing analysis will check that the screen is effective, enable screening improvement, indicate possible product and manufacturing improvements, and confirm screening remains necessary. It is recognized that as design and manufacture matures the need for product stress screening may decline. Screening was

traditionally used in the final testing of electronic devices, but with the much improved process control and automated fabrication demanded by huge electronic volumes, screening has been largely eliminated. Manufacturers demonstrated that screening was beginning to cause more damage than good.

Structural Models of Corporate Credit Risk

The Merton Model

The best way to introduce the structural approach starts with the Merton model (*see Credit Migration Matrices; Default Risk; Default Correlation; Credit Value at Risk*). This was the first structural model in the literature, and it contains the core idea of the approach. In fact, most recent models are extensions of the Merton model. Merton [1] considers that the asset value of a firm follows a geometric Brownian motion (GBM) (*see Insurance Pricing/Nonlife; Risk-Neutral Pricing; Importance and Relevance; Simulation in Risk Management; Weather Derivatives*) and assumes that the firm issues only one zero coupon (*see Options and Guarantees in Life Insurance; Credit Migration Matrices; Mathematical Models of Credit Risk*) corporate bond. Default is the event where the firm is unable to settle the promised payment upon the bond maturity.

Let V_t be the value of the firm's assets at time t , and K be the promised payment at maturity T , or the face value of the bond. If the firm value is higher than the face value on the maturity date, then equity holders will receive the residual value of the firm after paying back the debt; otherwise, they will receive nothing because the firm will declare bankruptcy and debt holders will own the firm. Hence, the payoff for equity holders on the debt maturity date is given by

$$\max(V_T - K, 0) \quad (1)$$

This payoff function is exactly that of the standard call option. Merton assumes a complete market and employs the Black–Scholes (BS) option pricing formula (*see Structured Products and Hybrid Securities; Default Risk; Statistical Arbitrage*) to obtain the market value of equity, S_t . More precisely, the asset price dynamics is postulated to be

$$\frac{dV}{V} = \mu dt + \sigma dW \quad (2)$$

where μ is the asset drift rate, σ is the volatility of the firm asset value, and W is the Wiener process. The BS formula is given by

$$S_t = V_t N(d_1) - K e^{-r(T-t)} N(d_2) \quad (3)$$

$$d_1 = \frac{\ln(V_t/K) + (r + \sigma^2/2)(T-t)}{\sigma\sqrt{T-t}},$$

$$d_2 = d_1 - \sigma\sqrt{T-t} \quad (4)$$

where r is the constant risk-free interest rate, and $N(x)$ is the cumulative distribution function of a standard normal random variable.

From the bond holders' perspective, on the maturity date, if the firm value is larger than the face value, then they will receive the face value; otherwise, they will obtain an amount equivalent to the firm's asset value. Hence, the payoff for bond holders is

$$\min(V_T, K) = K - \max(K - V_T, 0) \quad (5)$$

The present value of this corporate zero coupon bond can be fully replicated by a portfolio of a long position in a default-free bond and a short position in a put option. The default-free bond has a face value K and the put option has a strike price K and maturity T . Denote $B(t, T)$ as the corporate bond price. We have

$$B(t, T) = K e^{-r(T-t)} - K e^{-r(T-t)} N(-d_2) + V_t N(-d_1) \quad (6)$$

where d_1 and d_2 have been defined in equation (4).

Probability of Default

An objective in credit risk analysis is to measure the probability of default (PD) (*see Credit Scoring via Altman Z-Score; Credit Migration Matrices; Default Risk*) of a credit obligor. As the Merton model assumes that default only occurs on the maturity date of the debt, the default probability is the probability that the terminal asset value V_T is smaller than the face value K . This probability can be expressed in a closed form:

$$\begin{aligned} \text{PD} &= \Pr(V_T < K) \\ &= N\left(\frac{\ln\left(\frac{K}{V_t}\right) - \left(\mu - \frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right) \end{aligned} \quad (7)$$

As the Merton model considers the capital structure of the firm and the incentive issues of equity and

bond holders, it is known as a *structural model*. In the financial market, structural models are also known as *option-theoretic approaches* to credit risk. The Merton model shows that option pricing theory plays a key role in the formulation. We will see shortly that other structural models have similar characteristics, but relax some of the assumptions.

The major advantage of the Merton model is its analytical tractability. The trade-off is that the over-simplified assumptions limit the application of the model. First, it assumes a constant risk-free interest rate. As corporate bonds usually have long periods of maturity, a realistic model should incorporate a stochastic interest rate (see **Mathematical Models of Credit Risk**). Secondly, the Merton model only allows default to occur on the maturity of debt, but firms can default at any time in the real world. Thirdly, interim payments such as bond coupons are not considered in the analysis. Finally, the use of the GBM ignores the hazard of a sudden drop in asset value. Hence, it is important to develop models beyond Merton's idea.

First Passage Time Models

To allow firms to default at any time, Black and Cox [2] (see **Simulation in Risk Management; Default Correlation**) introduce the notion of a default barrier. When the firm value goes below a threshold, bond holders can enforce equity holders to declare bankruptcy. This indenture covenant for bond holders avoids further deterioration of the firm's asset value.

On top of the notation in the Merton model, let H be the exogenously specified default barrier (see **Credit Risk Models**) or distress level. In the Black–Cox model, equity holders receive the residual value of the firm if the terminal asset value is higher than the face value and the asset value never goes below the barrier prior to maturity. Suppose that only one zero corporate bond is issued by the underlying firm. The payoff for equity holders becomes

$$\max(V_T - K, 0)I_{\{\tau_H > T\}} \quad (8)$$

where I_A is the indicator function for the event A and τ_H is the first passage time: $\tau_H = \inf\{t : V_t < H\}$. This payoff function resembles the payoff of a down-and-out call (DOC) option. When the default-free

interest rate is a constant, there is a closed-form solution for the DOC option. Specifically,

$$\begin{aligned} S_t &= DOC(V_t, K, H) \\ &= V_t N(a) - K e^{-r(T-t)} N\left(a - \sigma\sqrt{T-t}\right) \\ &\quad - V_t (H/V_t)^{2\eta} N(b) + K e^{-r(T-t)} (H/V_t)^{2\eta-2} \\ &\quad \times N\left(b - \sigma\sqrt{T-t}\right) \end{aligned} \quad (9)$$

where

$$a = \frac{\ln(V_t/K) + (r + \sigma^2/2)(T-t)}{\sigma\sqrt{T-t}} \quad (10)$$

$$b = \frac{\ln(H^2/V_t K) + (r + \sigma^2/2)(T-t)}{\sigma\sqrt{T-t}} \quad (11)$$

$$c = \frac{\ln(H/V_t) + (r + \sigma^2/2)(T-t)}{\sigma\sqrt{T-t}} \quad \text{and} \quad (12)$$

$$\eta = \frac{r}{\sigma^2} + \frac{1}{2} \quad (13)$$

In equation (9), it is assumed that the strike price K is larger than the barrier H . If the barrier is higher than the strike price, then it is not reasonable for the firm to default when the barrier is hit, because the firm value is large enough to pay back the face value K .

We now consider the situation of bond holders. The face value will be received if the terminal firm value is higher than the face value and the firm value does not breach the downside default barrier. This payoff structure can be fully replicated by a portfolio of a long position in a default-free zero coupon bond with face value K , a short position in a put option with strike price K and a long position in a down-and-in call option with a barrier H and strike K .

Probability of Default

As default is triggered by the default barrier in first passage time models, the definition of the PD should be revised. Default is now viewed as the event that the firm value hits the downside barrier within a given time horizon. Mathematically, we write:

$$PD = \Pr(\tau_H < T) \quad (14)$$

If we adopt the GBM for the asset price dynamics, then a closed-form solution can be obtained for the PD:

$$N\left(\frac{\ln \frac{H}{V_t} - \left(\mu - \frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right) + \left(\frac{V_t}{H}\right)^{\frac{2\left(\mu - \frac{\sigma^2}{2}\right)}{\sigma^2}} \times N\left(\frac{\ln \frac{V_t}{H} - \left(\mu - \frac{\sigma^2}{2}\right)(T-t)}{\sigma\sqrt{T-t}}\right) \quad (15)$$

However, the PD cannot be obtained in closed form in general situations, such as the GBM with time-dependent coefficients.

The KMV Approach

Moody's KMV approach is a first passage time model. Although the actual formulation of the approach is proprietary, it is well known that it views the market value of equities as a perpetual DOC option: refer to [3] for technical details. The default barrier and the strike price are both set to the default point, which is defined as the sum of short-term debt and half of the long-term debt reported in a firm's financial statement.

The KMV approach estimates the default probability rather than valuing corporate bond prices. Therefore, the market value of equities will be used as an input to estimate the market values of the firm and its volatility. The PD then is the output of the system. The methods of estimating firm values and volatility will be detailed later.

Endogenous Bankruptcy

The first passage time models discussed so far are based on an exogenous default barrier. Leland and Toft [4] propose that it is possible to obtain the barrier level endogenously. The endogenous bankruptcy should be set at the level at which both the firm value and equity value are maximized. Bankruptcy costs, taxes, asset payout, and coupon payment are incorporated in the model in [4].

Suppose that the default barrier, H , is exogenously given. Under the GBM for the asset price process, Leland and Toft [4] determine the total value of all

outstanding bonds:

$$\begin{aligned} B(V; H, T) &= \frac{C}{r} + \left(K - \frac{C}{r}\right) \left(\frac{1 - e^{-rT}}{rT} - I(T)\right) \\ &\quad + \left[(1 - \alpha)H - \frac{C}{r}\right] J(T) \\ I(T) &= \frac{1}{rT} [G(T) - e^{-rT} F(T)] \\ J(T) &= \frac{1}{z\sigma\sqrt{T}} \left[-\left(\frac{V}{H}\right)^{-a_1+z} N(q_1)q_1 \right. \\ &\quad \left. + \left(\frac{V}{H}\right)^{-a_1-z} N(q_2)q_2 \right] \\ F(T) &= N(h_1) + \left(\frac{V}{H}\right)^{-2a_1-z} N(h_2) \\ G(T) &= \left(\frac{V}{H}\right)^{-a_1+z} N(q_1) + \left(\frac{V}{H}\right)^{-a_1-z} N(q_2) \end{aligned} \quad (16)$$

where

$$\begin{aligned} q_1 &= \frac{\ln \frac{H}{V} - z\sigma^2 T}{\sigma\sqrt{T}}; \quad q_2 = \frac{\ln \frac{H}{V} + z\sigma^2 T}{\sigma\sqrt{T}} \\ h_1 &= \frac{\ln \frac{H}{V} - a_1\sigma^2 T}{\sigma\sqrt{T}}; \quad h_2 = \frac{\ln \frac{H}{V} + a_1\sigma^2 T}{\sigma\sqrt{T}} \\ a_1 &= \frac{r - \delta - \sigma^2/2}{\sigma^2}; \quad z = \frac{[(a_1\sigma^2)^2 + 2r\sigma^2]^{1/2}}{\sigma^2} \end{aligned} \quad (17)$$

and δ is the asset payout rate, K is the total principal value of all outstanding bonds, C is the total coupon paid by all outstanding bonds per year, and α is the fraction of firm's asset value lost in bankruptcy; i.e., the remaining value $(1 - \alpha)H$ is distributed to bond holders in bankruptcy.

The total market value of the firm, v , equals the asset value V plus the value of tax benefits, less the value of bankruptcy costs. Tax benefits accrue at rate τC per year as long as $V > H$, where τ is the corporate tax rate. The total firm value is given by

$$\begin{aligned} v(V; H) &= V + \frac{\tau C}{r} \left[1 - \left(\frac{V}{H}\right)^{a_1+z} \right] \\ &\quad - \alpha H \left(\frac{V}{H}\right)^{-a_1-z} \end{aligned} \quad (18)$$

Hence, the market value of equity is given by

$$S(V; H, T) = v(V; H) - B(V; H, T) \quad (19)$$

To determine the equilibrium default barrier H endogenously, Leland and Toft [4] specify that the equity valuation formula should satisfy the smooth-pasting condition, under which the value of equity and the value of the firm are maximized. Specifically, H must be solved from the following equation:

$$\left. \frac{\partial S(V; H, T)}{\partial V} \right|_{V=H} = 0 \quad (20)$$

The solution is given by

$$H = \frac{(C/r)(A/(rT) - B) - AK}{(rT) - \tau C(a_1 + z)/r} \quad (21)$$

$$1 + \alpha(a_1 + z) - (1 - \alpha)B$$

where

$$A = 2a_1 e^{rT} N(a_1 \sigma \sqrt{T}) - 2z N(z \sigma \sqrt{T}) + (z - a_1) - \frac{2}{\sigma \sqrt{T}} n(z \sigma \sqrt{T}) + \frac{2e^{-rT}}{\sigma \sqrt{T}} n(a_1 \sigma \sqrt{T}) \quad (22)$$

$$B = - \left(2z + \frac{2}{z \sigma^2 T} \right) N(z \sigma \sqrt{T}) - \frac{2}{\sigma \sqrt{T}} n(z \sigma \sqrt{T}) + (z - a_1) + \frac{1}{z \sigma^2 T} \quad (23)$$

and $n(\cdot)$ denotes the standard normal density function. Once the endogenous barrier is obtained, the equity and bond pricing formulas are respectively defined in equations (16) and (18) with the endogenous barrier substituted into the formulas.

Implementation Methods

The challenge of implementing structural models is the estimation of the value and risk of the firm's assets, both of which are not directly observable. As the market values of equities are observable for listed corporations, it is the market convention to infer the market value of a firm from its equity values.

Once a structural model has been chosen, there is a one-to-one relationship between the equity and the firm's value. To allow general discussion, we write $S = S(V; \sigma, T)$ and our target is to estimate both V and σ from a given data set of equity values:

$\mathbf{S} = \{S_0, S_1, \dots, S_n\}$, where $S_i = S(t_i)$. For instance, if the Merton model is used, then the function $S(V; \sigma, T)$ is the European call option (*see Equity-Linked Life Insurance; Options and Guarantees in Life Insurance*) formula as in equation (3). If the Black-Cox model is considered, then it becomes the DOC option formula as in equation (9).

Variance Restriction

To implement the Merton model, Ronn and Verma [5] propose a variance-restriction method that can be applied to other models as well. The idea is to apply Ito's lemma on the equity pricing formula to derive a formula for the equity volatility. The estimation then requires that the observed equity price and volatility should match the model outputs.

Because it is assumed that the firm value follows GBM as in equation (2), invoking Ito's lemma on $S(V; \sigma, T)$ yields:

$$\frac{dS}{S} = (\dots) dt + \sigma \frac{V}{S} \frac{\partial S}{\partial V} dW \quad (24)$$

This implies that the equity volatility relates to the firm's asset value and its volatility by

$$\sigma_S = \sigma \frac{V}{S} \frac{\partial S}{\partial V} \quad (25)$$

where σ_S denotes the equity volatility. Together with the equity pricing formula, it forms a system of two equations at each observed time point t_i :

$$S_i = S(V_i, \sigma_i, T) \quad \text{and} \quad \sigma_S = \sigma_i \frac{V_i}{S_i} \left[\frac{\partial S}{\partial V} \right]_{V=V_i} \quad (26)$$

For the Merton model, the term $\frac{\partial S}{\partial V}$ can be explicitly calculated as $N(d_1)$, where d_1 is defined in equation (3).

We summarize the implementation procedure as follows:

- Step 1. Calculate the rate of returns from the sample $\mathbf{S} = \{S_0, S_1, \dots, S_n\}$ using the formula $R_i = (S_i - S_{i-1})/S_{i-1}$ for $i = 1, 2, \dots, n$.
- Step 2. Compute the sample equity volatility: $\sigma_S = \sqrt{\text{var}(R)/\Delta t}$.
- Step 3. Solve the system of equations (26) for $i = 0, 1, \dots, n$.

In step 3, a numerical root-finding method should be employed. Although this variance-restriction method is very efficient, it violates the constant volatility assumption for the firm value process. If the equity volatility is a constant, then from the second equation of (26) the firm value volatility must be a stochastic variable. Once σ is stochastic, the option pricing formula is no longer true. Although one immediately recognizes that this is theoretically inconsistent, see [6], this variance-restriction method is still the most common way to implement structural models so far.

Maximum-Likelihood Estimation

A more advanced approach uses statistical techniques to estimate the value and risk of the firm. Duan [7] proposes a maximum-likelihood estimation to structural models. The idea is to derive the likelihood function for equity prices subject to the constraint that the equity price matches the model price and the firm value follows a GBM.

Duan [7] derives the log-likelihood function as,

$$L(\mu, \sigma) = \sum_{i=1}^n \ln g(V_i | V_{i-1}) - \sum_{i=1}^n \ln \left[V_i \cdot \frac{\partial S}{\partial V} \Big|_{V=V_i} \right] \quad (27)$$

where

$$g(V_i | V_{i-1}) = \frac{1}{\sigma \sqrt{2\pi}} \times \exp \left(-\frac{[\ln(V_i / V_{i-1}) - (\mu - \sigma^2/2)(t_i - t_{i-1})]^2}{2\sigma^2(t_i - t_{i-1})} \right) \quad (28)$$

The estimation is achieved by maximizing the log-likelihood function numerically subject to the constraint:

$$S_i = S(V_i, \sigma_i, T) \quad (29)$$

Hence, the implementation requires numerical optimization methods provided by software. For example, the subroutines “fminsearch” and “fmincon” provided by MATLAB can be used to numerically maximize the likelihood function. Numerical examples can be found in [6, 7].

KMV Approach

The following approach is employed by KMV to estimate parameters in structural models: see [8].

- Step 1. Set an initial value of $\sigma = \sigma^{(0)}$ and $j = 0$.
- Step 2. Solve V_i from the equation: $S_i = S(V_i; \sigma^{(j)}, T)$ for $i = 0, 1, \dots, n$.
- Step 3. Set $j = j + 1$ and $\sigma^{(j)}$ to be the sample volatility of $\{V_0, \dots, V_n\}$.
- Step 4. Repeat steps 2 and 3 until $|\sigma^{(j+1)} - \sigma^{(j)}| < \epsilon$, for some small value ϵ .

When the algorithm stops at the j th iteration, we obtain an estimate $\sigma^{(j)}$ for σ and a set of estimated firm values $\mathbf{V} = \{V_0, \dots, V_n\}$. The drift μ can then be measured as the sample expected rate of return from the sample $\mathbf{V}$. A numerical example can be found in [8].

Structural Reliability

Structural systems (*see* **Mathematics of Risk and Reliability: A Select History**) such as buildings, bridges, water tanks, containment vessels, and communication towers are often represented as load-resistance systems. In all cases, these structures represent substantial and expensive assets that are unique or “one-off”. Even apparently, similar buildings have different occupancy loads, foundations, connection details, etc. Clearly, their reliability cannot be directly inferred from observation of failures or other experimental studies. In these circumstances, reliabilities need to be predicted from predictive models and probabilistic methods. As such, there is a clear recognition that uncertainty and variability are associated with many variables describing a structure’s performance and that this can be accounted for explicitly by the use of probability distributions and structural reliability theory (e.g. [1]).

Structural reliability theory underpins many recent advances in structural and safety engineering, namely,

- reliability-based calibration of design codes in Europe, United States, Canada, Australia, and elsewhere (e.g. [2]);
- performance-based design of new structures such as the Confederation bridge (Canada), Great Belt bridge (Denmark), and Messina Strait bridge (e.g., [3]);
- service life and safety assessment of existing structures (e.g. [4]);
- optimal maintenance of aging or deteriorating structures (e.g., [5]).

Although the emphasis of the present chapter is on structural engineering systems, the computational and probabilistic methods described herein are also appropriate for other load-resistance or demand-capacity systems, such as geotechnical, mechanical, hydraulic, electrical, and electronic systems where performance failure is deemed to occur when a predicted load/demand exceeds a resistance/capacity.

Limit States

Limit state functions (*see* **Reliability of Large Systems**) are used to define “failure”, and the definition

of failure can vary from person to person. A limit state is a boundary between desired and undesired performance. Undesired performance may take on many characteristics. For example, structural collapse of a bridge girder could be because of exceedance of flexural, shear or bearing capacities, fatigue, corrosion, excessive deflections or vibrations, and other modes of failure. Each of these modes of failure should be considered separately and can be represented by a limit state function. In general, limit state functions of interest are related to the following:

1. ultimate strength limit state – reduction in structural capacity
 - (a) strength
 - (b) stability.
2. serviceability limit state – loss of function
 - (a) deflection
 - (b) vibration
 - (c) fatigue
 - (d) cracking.

Calculation of Structural Reliability

Simple Formulation

If the limit state of interest is related to structural capacity, then failure is deemed to occur when a load effect (S) exceeds structural resistance (R). The probability of failure (p_f) is

$$\begin{aligned} p_f &= \Pr(R \leq S) = \Pr(R - S \leq 0) \\ &= \Pr(G(R, S) \leq 0) \end{aligned} \quad (1)$$

where $G()$ is termed the *limit state function*, and in the present case this is equal to $R - S$. Thus, the probability of failure is the probability of exceeding the limit state function. Note that R and S must be in the same units. The formulation given by equation (1) also holds for other limit states; for example, for excessive deflection, the “load effect” S is replaced by the actual deflection (δ), and “resistance” R represents the allowable deflection limit (Δ_L), such that equation (1) is rewritten as

$$p_f = \Pr(\delta \geq \Delta_L) = \Pr(\Delta_L - \delta \leq 0) \quad (2)$$

The following discussion will use the classic R and S notation to illustrate the key concepts of structural reliability.

The strength of identical structural components will vary from component to component because of variabilities in material properties, geometric dimensions, environmental conditions, maintenance, etc. Similarly, loadings are influenced by a variety of factors, such as environment, temperature, geographic location (wind, earthquake), etc., which are time dependent and often highly variable. Consequently, resistance and loads (and their influencing variables) should be modeled as random variables.

For the simplest case with one random variable for load (S) and another for resistance (R), the probability of failure is given by the well-known “convolution” integral

$$p_f = \int_{-\infty}^{\infty} F_R(x) f_S(x) dx \quad (3)$$

where $f_S(x)$ is the probability density function of the load S and $F_R(x)$ is the cumulative probability density function of the resistance [$F_R(x)$ is the probability that $R \leq x$]; see Figure 1. Note that failure probability may be calculated per annum, per lifetime, or for any other time period. It follows that the probabilistic models selected for loads and resistances must relate to this time period. For example, the lifetime reliability for a communications tower requires that the probabilistic model of the maximum wind speed to be experienced over the lifetime of the structure is known.

For elementary cases, the integration of equation (3) is not difficult. For the special case where R and S are both normally distributed with means μ_R and μ_S and variances σ_R^2 and σ_S^2 , the probability of failure (see **Imprecise Reliability; Reliability**

Data) is expressed simply as

$$p_f = \Pr(R - S \leq 0) = \Phi\left(\frac{-(\mu_R - \mu_S)}{\sqrt{\sigma_S^2 + \sigma_R^2}}\right) = \Phi(-\beta) \quad (4)$$

where $\Phi()$ is the standard normal distribution function (zero mean, unit variance) extensively tabulated in statistics texts and β is the “reliability index” (see **Reliability Optimization; Quantitative Reliability Assessment of Electricity Supply**). In structural reliability literature, particularly reliability-based calibration of codes, the reliability index is often used as the measure of safety. The relationship between probability of failure p_f and reliability index β is shown in Table 1.

For example, let us assume that a steel bridge girder of length 15 m is loaded with an annual peak mean uniformly distributed load (w) of 16 kN/m. The mean flexural strength of the girder is 950 kNm with coefficient of variation (COV) of 0.1. The variability of loading is higher with a COV of 0.18. From elementary structural theory, the applied moment (load effect S) for a simply supported beam is $wL^2/8$. If self-weight of the beam is ignored, the structural reliability calculations based on equation (4) are as follows:

$$\begin{aligned} \text{Resistance (R):} \quad & \mu_R = 950 \text{ kNm} \\ & \sigma_R = 0.1 \times 950 = 95 \text{ kNm} \\ \text{Load Effect (S):} \quad & \mu_S = \frac{16 \times 15^2}{8} = 450 \text{ kNm} \end{aligned}$$

Figure 1 Basic $R - S$ problem showing $f_S(x)$ and $f_R(x)$

Table 1 Relationship between probability of failure p_f and reliability index β

p_f	β
10^{-1}	1.28
10^{-2}	2.33
10^{-3}	3.09
10^{-4}	3.71
10^{-5}	4.26
10^{-6}	4.75
10^{-7}	5.19
10^{-8}	5.62
10^{-9}	5.99
10^{-10}	6.36

$$\sigma_S = 0.18 \times 450 = 81 \text{ kNm}$$

Reliability Index:

$$\begin{aligned} \beta &= \frac{\mu_R - \mu_S}{\sqrt{\sigma_R^2 + \sigma_S^2}} \\ &= \frac{950 - 450}{\sqrt{95^2 + 81^2}} = 4.01 \end{aligned}$$

Probability of Failure: $p_f = \Phi(-\beta)$

$$= 3.05 \times 10^{-5} \text{ per year}$$

If corrosion on the bridge is observed with a 10% reduction in mean strength to 855 kNm and same statistics for loading, then $\beta = 3.44$ and the corresponding probability of failure increases by nearly 10-fold to 2.91×10^{-4} per year.

General Formulation

For many realistic problems, the simplified formulation given by equation (3) is not sufficient as the limit state function often contains more than two variables. Usually, several random variables will influence structural capacity, such as material properties, dimensions, model error, etc. Moreover, there are likely to be several load processes acting on the system at the same time. For example, these might be wind, wave, temperature, and pressure forces acting on an offshore structure. For instance, the limit state for a steel bridge girder can be expressed as

$$G(\mathbf{X}) = R - S = F_y Z - (D + L_p) \quad (5)$$

where the vector $\mathbf{X}$ represents the basic variables involved in the problem, in this case, F_y (yield strength) and Z (elastic modulus) representing the bridge girder resistance, and D and L_p representing the dead and peak vehicle live loads, respectively.

If the limit state function is expressed as $G(\mathbf{X})$, the generalized form of equation (3) becomes

$$p_f = \Pr[G(\mathbf{X}) \leq 0] = \int \dots \int_{G(\mathbf{X}) \leq 0} f_{\mathbf{X}}(\mathbf{x}) d\mathbf{x} \quad (6)$$

where $f_{\mathbf{X}}(\mathbf{x})$ is the joint probability density function for the n -dimensional vector $\mathbf{X} = \{X_1, \dots, X_n\}$ of random variables each representing a resistance random variable or a loading random variable acting on the system. Figure 2 shows a representation of a joint probability density function for two variables R and S , and the probability of limit state

Figure 2 Region of integration for failure probability [Reproduced from [6]. © Chapman & Hall (The Thompson Group), 1997.]

exceedance (see **Bayesian Statistics in Quantitative Risk Assessment**).

The solution to equation (6) is complex, particularly because resistance and loading variables often vary in time and space (such as corrosion, fatigue, or other sources of deterioration), the variables may be correlated, and most infrastructure comprises many elements or components requiring a systems approach to infrastructure performance. Two main approaches can be taken to solve equation (6):

1. Analytical methods by transforming $f_{\mathbf{X}}(\mathbf{x})$ to a multinormal probability density function to approximate the failure region of the limit state function – second moment and transformation methods such as first-order second moment (FOSM) and first-order reliability methods (FORM) (see **Insurance Pricing/Nonlife**).
2. Numerical approximations to perform the multidimensional integration required in equation (6) – Monte Carlo simulation techniques (see **Ruin Probabilities: Computational Aspects; Simulation in Risk Management; Systems Reliability; Expert Elicitation for Risk Assessment**) that involve random sampling each random variable. The limit state $G(\mathbf{X})$ is then checked enabling p_f to be inferred from a large number of simulation runs.

These methods may be difficult to implement for all except trivial problems. For this reason, a large array of software packages are available – see Pellissetti and Schueller [7] for a review of available software.

All the methods are not of equal accuracy or applicable to all problems. Second moment and transformation methods are computationally very efficient and often very useful for most problems. They do have disadvantages, however, that nonlinear limit state functions are not easily handled and may give rise to inaccuracies, and difficulties can arise in using nonnormal random variables and dependencies. On the other hand, simulation methods are, in principle, very accurate, can handle any form of limit state function, and are not restricted to normal random variables. However, the computational times can be significant because of the high number of simulation runs often needed to produce convergent results. Nonetheless, with the availability of computers with ever increasing speed and the use of importance sampling, response surface methods, and other variance reduction techniques, the computational efficiency of simulation methods can be greatly improved.

Additional Capabilities of Reliability Analysis

The theoretical framework for structural reliability analysis is well established, and the formulation given by equation (6) can be broadened to encompass the following:

- structural systems comprising many components whose resistance or loading are correlated;
- stochastic processes
 - time-dependent process that arise from fatigue, corrosion, change in use, etc.;
 - spatial variability that arise from nonhomogeneous material, dimensional, or other properties;
- updating information from existing structures;
 - Bayes theorem;

- proof and service load information;
- acceptance criteria for new and existing structures.

It is beyond the scope of this article to describe structural reliability theory in detail. For an introductory text on fundamental probability and structural reliability theory and typical reliability-based applications, see Nowak and Collins [8]. More advanced structural reliability theory is described by Ditlevsen and Madsen [9] and Melchers [10].

MARK G. STEWART

Structured Products and Hybrid Securities

A “structured product” is a derivative financial security, whose cash flows are “structured” to depend on more basic financial values, so as to suit the parties to the arrangement. An example is a guaranteed equity bond (GEB), which might be issued with a lifetime of 5 years, at the end of which the principal invested is paid, plus say 90% of any gain, if the principal had been invested in the stock index over the 5 years and if this gain is positive. This product is structured to match the risk profile of an investor who wants to participate in any gains in the stock market but who does not want to risk losses. As is typical with structured products, the GEB is “hybrid” in nature, since it combines the upside potential of equity with the certainty of a bond.

In this survey, some of the main categories of structured products and the motivation for their design are described, and the valuation and risk management of these products are briefly discussed.

Structured Notes

A structured note allows an issuer to borrow at a very low rate, by including a structure that suits the risk appetite of the investor. Crabbe and Argilagos [1] give an overview of this market. For example, an investor might have the view that interest rates will fall over the next 5 years. A 5-year inverse floating rate note (IFRN) with interest payments being a fixed rate F minus 6-month LIBOR (the LONDON INTERBANK OFFERED RATE) allows him to benefit, if his view is correct. LIBOR is essentially the riskless rate for borrowing for a short period, which is 6 months in this case. LIBOR is set at the beginning of each 6-month interest period, and the investor believes that this rate will fall over the next 5 years.

The investor asks an investment bank to find a borrower who is prepared to issue such a note. An issuer might be able to issue straight debt with coupon of 8%, and if the 5-year swap rate is say 6%, then he will benefit if he can set $F = 13.9\%$ above. To explain this, swapping cash flows at the fixed swap rate, for LIBOR, is a fair (zero net present value)

transaction, and so the issuer should expect to pay $14\% (= 6 + 8\%)$ minus LIBOR with this structure. However, the investor is prepared to receive just 13.9%, since this structure allows him to implement his prediction on interest rates.

The issuer can reverse out of this structure, by separately entering a swap agreement to pay LIBOR and receive 6%. So the issuer is not in the end exposed to interest rate risk. Also, it should be noted that the investor will only benefit to the extent that he outpredicts the market itself, since the swap rate of 6% incorporates the markets view of the movements of LIBOR over the coming 5 years.

Many similar examples are given in Das [2]; for example, a 5-year note might make coupon payments every 6 months, based on the value of the 5-year CMT (constant maturity treasury) rate at each interest date. This CMT rate is a published benchmark rate for borrowing for 5 years. It would be more natural to have the interest rate determined by 6-month LIBOR in this note to match the interest period. This structure might be motivated as a play on the slope of the yield curve, as represented by the difference between the 6-month and the 5-year rates.

The commodity linked structured products market has grown significantly in recent years. Commodity linked notes provide investors a return that is linked to the performance of a basket of commodities. Typically these products are 100% principal protected; the return is linked to the positive return of the basket and investors are protected from negative returns. The underlying baskets for these products can be quite varied – the basket may contain just a few key energies and metals, for example crude oil, natural gas, aluminum, copper, nickel; or they may be a very broad basket of soft commodities such as wheat, corn, soybeans, cotton, sugar, coffee, cocoa, cattle, and hogs.

Perhaps the most notorious structured product was that agreed upon between Bankers Trust (BT) and Proctor and Gamble (P&G), in November 1993. This has been analyzed in detail in Smith [3], and the details have become public only because it became the subject of legal action involving these counterparties.

Basically, the arrangement was agreed to run for 5 years with a principal of US\$200 million, and involved a “swap” and a “spread”. Under the swap, P&G would pay to BT every 6 months the commercial paper (CP) rate minus 75 basis points

(i.e., 0.75%), and receive a fixed rate of 5.3%. The CP rate is a floating interest rate that high-grade borrowers might expect to pay. Assuming that P&G could have borrowed at 5.3% over this 5-year period, this swap is advantageous to them, with the value given by the 75 basis point interest adjustment for 5 years. Bundled with P&G borrowing at a fixed rate, this arrangement is equivalent to a structured note (see **Statistical Arbitrage**).

The spread was given by the formula $\max \left\{ 0, (98.5 \times \frac{5\text{-year CMT\%}}{5.78\%} - (30\text{-year TSY}))/100 \right\}$, in which (30-year TSY) is the price of the treasury bond with a coupon of 6.25% and maturity of August 2023. P&G would pay this every 6 months, starting from the first year, i.e., November 1994, although its value would be fixed according to rates at 6 months after issue, i.e., in May 1994.

This spread can be understood as an option written by P&G, equivalent to a bet that interest rates would not rise, since they would have to pay if either the 5-year rate or the 30-year rate rose. Their premium for this resides in their favorable terms on the swap.

What made this deal so notorious was that it was so aggressive, and blew up so spectacularly. Interest rates rose before May 1994, with the 5-year CMT rate rising from 5.02 to 6.71%, and the 30-year bond yield rising from 6.06 to 7.35% (price falling from \$102.57811 to \$86.84375). Putting these numbers into the formula, P&G has to make interest payments of 27.50% for $4\frac{1}{2}$ years, on a principal of \$200 million, putting them underwater by about \$200 million. P&G initiated legal action against BT but they settled out of court. Arguably, this episode fatally wounded the reputation of BT, and they were taken over by Deutsche Bank in 1999. Smith subjects this deal to a rigorous evaluation, and concludes that, apart from the exposure entailed, the value of the swap was not enough to compensate P&G for the option they were writing.

Callable and Convertible Bonds, US Style Prepayable Mortgages

A convertible bond (CB) is issued by a company to raise capital, and it is a bond, but the holder has the option to convert the bond into new equity, which will then be issued by the company, at a ratio that is prespecified in the CB contract.

With structured securities, often the question of motivation for creating the security is a challenge, and with respect to the CB this has been given a fascinating answer by finance theorists. At first glance, a CB offers cheap financing: a firm might have a share price of \$70, and the ability to issue straight bonds with coupon of 8%. Such a firm might be able to issue CBs with a coupon of 4%, convertible into shares corresponding to a price of \$100, i.e., if the CB has principal of \$1000, then it is convertible into 10 shares (see Brennan and Schwartz [4]). Thus, the company is paying a low interest rate if the bonds are not converted, and it has issued equity at a premium, if the bonds are converted. However, this way of reasoning ignores the value of the optionality in the CB. This CB can be more accurately understood as being 50% bond and 50% an option to buy 10 shares for \$100 each. This option has value, although it is initially out of the money, i.e., it would not be rational to exercise the option immediately.

Current thinking is that CBs are in general correctly priced in the market, and they allow the firm to issue bonds, but to retain flexibility over its business strategy (see Green [5]). Such flexibility in conjunction with issuing a straight (i.e., not convertible) bond could lead to an “asset substitution problem” (see Jensen and Meckling [6]). If the firm issues straight debt and then chooses a more risky investment strategy, the benefits arising from success will accrue mostly to equity, because payments to debt are limited, but the losses arising from failure will fall disproportionately on the debt, if the firm becomes bankrupt, since the debt might not be paid back. Anticipating these outcomes, choosing a more risky strategy will then have the immediate effect of increasing the equity value at the expense of the debt value. And anticipating that the firm might increase the riskiness of their investment, the market will in any case demand a higher interest rate on the debt. Issuing a CB can avoid this problem, because the CB can participate in the upside potential of the investment, *via* being converted. This line of reasoning can explain why CBs are mostly issued by high-risk, high-growth firms.

Corporate bonds are sometimes “callable”, i.e., they can be redeemed before maturity (“called”) by the issuer, at a prespecified price, often their par value. In the past few years, the rationale for this feature might have been to allow for the orderly

retirement of the debt, but this rationale is increasingly moot as bond markets become more liquid, so that companies can buy their bonds in the market without causing any price distortions. A more current rationale might be to allow the issuer to benefit if interest rates fall, in which case the issuer can call the bonds, and concurrently issue more bonds at a lower rate.

A variation of the CB is the liquid yield option note (LYON), which is puttable by the investor, and callable by the issuer, as well as being convertible. McConnell and Schwartz [7] analyze this structure in detail, and show that some actual issues were reasonably priced in the market at initiation.

US style mortgages are fixed rate, and the mortgagee has the option to “prepay”, i.e., to pay off the mortgage at any time, by paying the amount outstanding according to the amortization schedule. If it is considered that taking out a mortgage is similar to issuing a bond (both are borrowing money), then the prepayment option is similar to the call feature on a bond. Also, a similar rationale applies, in that the mortgagee can prepay and refinance, if the interest rate falls. Other reasons for prepaying a mortgage include selling the mortgaged property or having a windfall gain.

Structured Retail Products

Equity based products that are structured to appeal to retail investors are broadly termed equity linked notes (ELNs). Das [2] categorizes these into principal protection vehicles and yield enhancement vehicles. The GEB mentioned above is an example the former. Das [2, pp. 526–527] gives an example of the latter. This is a 1-year note with a high coupon of 16.5%, but with maturity payment given by the principal, minus the gain that the principal would have made if it had been invested in the Nikkei 225 index, if this is positive. Thus, the investor has sold a call on the Nikkei index, and is being paid for this in the shape of the high coupon.

Many variations on these structures are possible. For example, an ELN might pay the return earned by investing a certain principal in the stock index, but with the return capped at some limit. In return for accepting a limited upside potential, the investor can buy the ELN at a discount from the principal. ELNs following these designs now trade on the Chicago Board Options Exchange and other exchanges.

An interesting structured retail product is the Swing Guaranteed Fund, designed by Societe Generale and issued in September 2002. This makes dividend payments at 1.0, 2.0, 3.0, and 4.5 years, based on a globally diversified portfolio of 18 stocks, and also pays back the principal invested after 4.5 years. The dividends are proportional to the minimum absolute return of the stocks in the portfolio, over each dividend period. Thus, the investor will benefit if the global markets are volatile, whether they rise or fall. Similarly complex products, involving many equities, are described by Quessette [8] and Overhaus [9].

The following discussion shows that valuation and risk management of such structures is more challenging than all the structures mentioned previously, because this depends on the individual movements of many prices.

Valuation and Risk Management

Many structured products are easy to separate into standard products. For example, the GEB discussed above can be decomposed into a bond, and a call option: if say \$100 is invested in the GEB, the bond pays \$100 at the 5-year maturity and no coupons, and the option pays $\$90 \times \max \left\{ \frac{S_t - S_0}{S_0}, 0 \right\}$, where S_t is the value of the index at time t . The \$100 principal here can be decomposed into the prices of the bond, and of the option, plus the profits received by the issuer, and the “participation rate” of 90% will be fixed, so that these do not exceed \$100.

For pricing and risk management of this structure, the main challenge is the option component. Since the maturity of 5 years is very long, there is no liquid market for such an option, and so the issuer cannot simply buy this option in the market, and must “synthesize” it *via* dynamically maintaining a position in the underlying index or corresponding futures contract, and borrowing/lending (see Hull [10]). This strategy might naively be done using the Black and Scholes [11] framework, but this will not be sufficiently accurate, because of the very long maturity. The issuer will have to synthesize the option in a manner that takes into account the interest rate risk, volatility risk, and the “smile effect” (see **Volatility Smile**), which is a well-recognized distortion in equity option markets.

Valuing and hedging (risk management), generally in financial markets, which can include equities, interest rates, currencies and commodities, is presented in a unified framework by Duffie [12]. This framework can be regarded as an extension of the Black–Scholes model, and similar partial differential equations (PDEs) hold to value derivatives, with each source of risk being a variable in the equation. To solve the PDE, the modeler might use an analytic formula, or a numerical procedure, or a Monte Carlo (MC) simulation. Of these, MC is the most cumbersome, but it is the only feasible one if there are more than about three-state variables.

Within this framework, interest rate modeling presents its own challenges, because there are many interest rates, and these have to be reduced to a manageable number of state variables. See Ho and Lee [13] for a survey of interest rate models. To price and hedge P&Gs structure, a two-factor interest rate model would probably be adequate, calibrated to the 5- and 30-year maturities, and the model would also enable the user to hedge the risks *via* a dynamic strategy using say the 5-year T Note and the T Bond futures contracts. To deal with a callable bond or prepayable mortgage, a one-factor model might be adequate, and to deal with a CB, an extra factor, representing the underlying stock value, should be included.

Of all the structures described above, the Swing Guaranteed Fund is perhaps the most difficult to price and hedge. This is because the underlying stocks represent 18 state variables, and these may not be reduced to a smaller number. MC simulation must be employed, and to hedge this structure, the modeler must maintain dynamic positions corresponding to the 18 stocks.

Subjective Expected Utility

For choosing a course of action, it is paramount that a “score” is assigned to each possible alternative, if not explicitly, at least implicitly. *Subjective expected utility* aims at determining how such a representation of our choices is possible, given the type and structure of our preferences. The earliest attempts started with the least difficult case and assumed that some probability distribution of the possible consequences existed beforehand. The “objective” or “frequentist” concepts of probability were invoked [1, 2]. We refer below briefly to these earliest attempts, for the concepts ironed out there have conditioned the later developments of SEUs and also because they are often of practical interest. Yet, the first *genuine* SEU generalizations [3–5] allowed to depart from situations of risk (i.e., known probabilities) and to face situations of uncertainty.

This article follows the above development path in the four first sections and ends with a discussion and some more recent advances in the last section.

Early Contributions

Less than 60 years after Pascal had formally expressed *expected gain* as a rule of evaluation in risky issues, Nicolas Bernoulli spread all over Europe the word, in the letter dated September 13, 1709, that Pascal’s rule was being violated by the subjects he had tested at St Petersburg’s imperial court: to participate in a parlor game, the expected gain of which was infinite, members of the court did not want to pay more than a few gold coins (“St Petersburg paradox”). Many solutions were offered in the late 1720s and until 1777, but the one that has been postulated by Daniel Bernoulli has been popular: when amounts at stake are large with respect to the decision maker’s assets, gains and assets should not be evaluated in plain money terms, but by a psychological appraisal of the accrual to the assets, named *emolumentum* [1] and later translated as *utility* (see **Utility Function**). The “paradox” was solved and a first version of the *expected utility* rule was postulated.

When looking for an evaluation of lotteries in a risky world, von Neumann (von Neumann and Morgenstern (henceforth vNM)) exhumed Bernoulli’s work, but gave it a more formal foundation [2]. In what follows, the term *prospect* (or *lottery with a finite number of consequences*) is taken to be the formal representation of a risky bet, including in technology, marketing, etc. von Neumann and Morgenstern argued that these prospects are inscribed in a “mixture space”, meaning that, from two lotteries A and B, it is always possible to construct a third one, written as $\alpha A + (1 - \alpha) B$, which we shall call a “convex combination” of lottery A and lottery B. The combined lottery belongs, in the probability space (simplex), to the segment of line linking the two points representing A and B. The virtue of assuming a mixture space is twofold: (a) In the simplex, the set of lotteries is convex and (b) if one lottery has as an outcome a ticket opening the possibility to play another lottery, this “two-stage” lottery can be represented by a “one-stage” lottery (“compounding lotteries”). vNM’s three axioms can now be presented as follows:

vNM1 (weak ordering)

The individual’s preferences can be represented by a complete, reflexive, and transitive relation between all lotteries, denoted by $\succsim$ and read as “not preferred or indifferent to”. If some engineer, for example, does not judge some risky technique T° as preferable to another one, say T^* , while seeing it as preferable to T , then $T \succsim T^\circ \succsim T^*$ and this implies $T \succsim T^*$ (transitivity). In proper mathematical terms, this binary relation is a complete preorder.

The next question refers to the existence of *indifference loci* of lotteries. Such an existence is postulated through a peculiar *continuity* property of preferences (axiom vNM2).

vNM2 (Archimedean property)

For any three lotteries such as L_1, L_2, L_3 , s.t. $L_1 \prec L_2 \prec L_3$, there always exists a real number λ between 0 and 1, such that $L_2 [\lambda L_3 + (1 - \lambda)L_1]$. In other words, a lottery like L_2 is always indifferent to some convex combination of a preferred lottery like L_3 and of a less preferred lottery like L_1 . Of course, the numerical value of λ depends not only on L_3 and L_1 but also on the *behavior toward risk* of the individual (see **Risk Attitude**).

Under these hypotheses and axioms, it can be shown that some real-valued index (a score function, defined up to any monotonically increasing transformation) $U(\cdot)$ exists on the set of lotteries, such that, from the point of view of the individual

$$L_1 \preceq L_2 \iff U(L_1) \leq U(L_2) \quad (1)$$

We have to make this result operational and find some way to determine the numerical values of $U(\cdot)$ i.e., to “encode” the U function, through some additional restrictions. Axiom vNM3 does the job.

vNM3 (independence)

Given any lottery M , and two lotteries L_1 and L_2 , such that $L_1 \preceq L_2$, any $\alpha \in [0, 1]$ will yield

$$\alpha L_1 + (1 - \alpha)M \preceq \alpha L_2 + (1 - \alpha)M \quad (2)$$

vNM3 can be interpreted as a separability axiom, for one can see that the outcomes of M do not play any role in equation (2). It has turned to be the most controversial axiom of all three above and is at the root of Allais’s paradox. It is closely related to the “sure thing principle” formulated by Savage (see the section titled “Savage’s Contribution”). vNM’s theorem then reads as follows [2].

Consider any lottery $L = (x_1, p_1; \dots; x_n, p_n)$. Denote by $u(x_i)(i = 1, \dots, n)$ the restriction of $U(\cdot)$ to degenerate lotteries like $(x_1, 1), \dots, (x_i, 1), \dots, (x_n, 1)$. Then, under vNM1–vNM3, whatever the feasible set of lotteries, the individual chooses the lottery L for which

$$U(L) = \sum_{i=1}^n p_i \cdot u(x_i) = E[u(\tilde{x})] \quad (3)$$

takes its maximal value in the feasible set. The $u(\cdot)$ function is called a *vNM utility function*, and is defined up to a positive affine transformation. This last point is essential: Neumannian expected utility (EU) scores are not “measures” in the strong mathematical sense (like absolute temperature in physics) but are *interval scales* (like the Fahrenheit or Celsius temperature scales). This plays an important role in management applications to reach some economic efficiency. Indeed, ratios of EU differences are well-defined numbers, which allows for an easy optimal allocation of resources among potential actions (including in enterprise risk management; (see **Enterprise Risk Management (ERM)**)).

Applications to *portfolio theory* have developed since the 1950s through a particular specification of the utility function (see **Utility Function**): the quadratic utility. It is then straightforward to show that EU is a function of $E(\tilde{R})$ and of $\sigma(\tilde{R})$, where $\tilde{R}$ denotes the return of financial shares [6]. Since the late 1970s, experimental methods have been considerably improved to encode vNM utility functions through individual elicitation methods [7]. This has considerably developed potential applications in *industrial management*, for which objective probabilities rarely exist.

Savage’s Contribution

Early in the nineteenth century, Keynes [8] and Knight [9] had forcefully argued that the *kind* of uncertainty facing *entrepreneurs* was different from the one facing a roulette gambler. Ramsey [10] expressed the idea that probabilities could be inferred from watching an agent’s behavior, while de Finetti [3] provided us with an operational theorem to do so, and with a definition of subjective probability. Assume that I own some 20Mio\$, and I am receiving an additional sum of 1000\$ if my horse wins the next *Grand Prix*. By then, my subjective probability of my horse winning is my *ex ante* conditional price of receiving the 1000\$.

Savage [4] achieved a synthesis between vNM and the above quoted authors, with all the weight of the difficulty put on the axioms of *individual* rationality. Then, let S be the (infinite) set of *states of the world* s (a state of the world entails everything that might have an impact on the consequences of an act, conditional on the state of the world that is obtained, and is thus a complete resolution of uncertainty). *Events* are subsets of S and C is the set of consequences. We now define an *act* as a *function* $f(s)$ from the set of states S to the set of consequences C , with no probability on S . The set of acts F is the set of all possible $f(s)$.

When we consider two different acts, say $f(s)$ and $g(s)$, and some event $E \subset S$, we can always think of a new act $f_E g$ with the following definition:

$$\text{For all } s \in E, f_E g(s) = f(s) \quad (4)$$

$$\text{For all } s \notin E, f_E g(s) = g(s) \quad (5)$$

For example, E is the event “horse H wins”. If the act $f(\cdot)$ is “betting on H” and the act $g(\cdot)$ is “betting

on horse K”, then $f(s)$ would yield the best prize only if $s \in E$, $g(s)$ could do so only for some state of the worlds such that $s \notin E$, while $f_E g(s)$ would do like $f(s)$ if $s \in E$ but also like $g(s)$ if $s \notin E$.

A null event E° is then an event that is so unlikely that it would not make any difference between $f_E g(\cdot)$ and $f'_{E'} g(\cdot)$, for all f, f' . Clearly, the empty set $\emptyset$ is a null event.

A constant act $\chi(c)$ is an act that assigns the same consequence, namely c , to every state of the world.

Savage’s contribution [4] has been to show that, under the conditions below described by postulates, the following holds:

(CS1) Under $P1$ – $P5$, there exists on the set of all possible events a transitive and complete binary relation $\geq$, which can read “at least as likely to obtain as”. This binary relation is a qualitative probability, for it preserves the additivity property, i.e.,

$$E \geq E' \iff E \cup D \geq E' \cup D, \quad \text{provided } E \cap D = E' \cap D = \emptyset \quad (6)$$

(CS2) By the continuity properties implied by the axioms below (in particular, by axiom $P6$), the qualitative probability relation of (CS1) becomes a unique subjective probability distribution.

(CS3) Preferences on acts generate preferences over probability distributions that are analogous to vNM preferences under risk, which were examined in the introductory section. Such preferences lead to the expected utility rule of rational choice under risk.

Note that (CS1) is intimately related to a previous work by de Finetti [3] and that (CS3) pertains to the work by von Neumann [2]. Part (CS2) is therefore the great achievement of Savage’s contribution, which provided the theory of subjective probability (see **Subjective Probability**) with the first strong foundation in the history of thought since subjective probabilities were first evoked [11].

By skipping some purely technical conditions here, we can formulate and give intuitive meaning to Savage’s axioms in our own way as under.

P1 (weak ordering on acts)

The individual we consider here has a complete, reflexive, and transitive binary relation $\succsim$ on acts.

P2 (sure thing principle)

For all acts f, f', h , and h' and every event E :

$$f_E h \succsim f'_E h \iff f_E h' \succsim f'_E h' \quad (7)$$

This amounts to saying that the modification that changes f into f' (which is obviously the same on the right- and the left-hand side of equation (6) and which impacts only the consequences of $f_E h$ on event E , consequences that change into the ones of $f'_E h$) explains *all* the reasons why $f_E h \succsim f'_E h$. Thus, there seems to be an argument that the valuation of the consequences of any act for some event E is independent of the valuation of the consequences of that act for the complementary event(s), which refers to mathematical separability. The reader could compare this with vNM3 (*independence axiom*) above and conclude that the Sure Thing Principle of Savage implies logically in vNM. The reader should compare with vNM3 (*independence axiom*) above and admit that the sure thing principle in Savage implies the independence axiom in vNM. As for practical implications, let us remark that $P2$ is a sufficient condition to justify that we may “roll back” a decision tree.

This postulate has, nevertheless, triggered persistent criticisms, following *Allais’ paradox* (see [12]). *Ellsberg’s paradox* can also be presented as a case of violation of this postulate [13].

P3 (conditional preferences)

For every nonnull event E and for all constant acts $\chi(c)$ and $\chi(c')$:

$$\chi(c)_E f \succsim \chi(c')_E f \iff c \succsim c' \quad (8)$$

This axiom embodies several ideas. In equation (8) we mean that the individual has preferences “on the consequences of E ”, i.e., *conditional preferences*, because, in the light of $P2$ above, the preference on constant acts can be associated to the preference “if E obtains”, E being nonnull. We also mean that this preference on constant acts is equivalent to a preference on consequences, which can be appraised *under certainty* as well, namely, c and c' , as expressed by the right-hand side of equation (8). This last point has been questioned by the authors of more general theories (state-dependent preferences), for it implies that the rank order of the consequences is independent from the underlying event [14]. However, $P3$ quite clearly suggests that if an act has for

an event E consequences that are in the view of the decision maker preferable than the ones in the E^c , selecting that act should be interpreted as a “bet on E ”, i.e., E is seen as more likely than E^c . Such a bet should neither depend on the absolute nor on the relative levels of c and c' . This is paramount to saying that preferences on acts induce judgments on the probabilities of events.

P4 (independence of tastes and beliefs)

For all events E and E' and constant acts $\chi(c)$, $\chi(d)$, $\chi(c')$, $\chi(d')$, with $c > d$, $c' > d'$:

$$\begin{aligned} \chi(c)_E \chi(d) &\succeq \chi(c)_E \chi(d) \\ \iff \chi(c')_E \chi(d') &\succeq \chi(c')_E \chi(d') \end{aligned} \quad (9)$$

Again, the authors of state-dependent preferences do not accept that axiom as is, because it implies that risk attitude (see **Risk Attitude**) is state independent. But *P4* clearly implies that tastes are independent of beliefs.

P5 (nontriviality)

For some constant act $\chi(c)$, there is at least one c' such that

$$\chi(c') > \chi(c) \text{ or } \chi(c) > \chi(c') \quad (10)$$

Under *P1–P5*, part (CS1) of Savage’s contribution holds. Going beyond this qualitative result requires some continuity condition on the preferences. It would seem reasonable to postulate that if two acts are very close to one another, they should be ranked the same with respect to a third act and that there exist partitions of events into as many null events as we want, which will rule out any “atomicity” (concentration on one point) of the probability measure on events. Formally,

P6 (continuity of preferences)

For all acts f , g , and h with $f > g$, there exists a finite partition $\{E_i, i = 1 \dots n\}$ of the set of states such that, for all i , $f >_{E_i} h$ and $h_{E_i} f > g$.

Under *P1–P6*, there exists a nonatomic probability measure on the set of states, which is defined on the set of events, i.e., finitely additive. This is the (CS2) part of Savage’s work, the most important one, as already mentioned.

Finally, Savage requires just one more axiom to confirm (under a much more general settings,

admittedly) the von Neumann–Morgenstern results of the introductory section. This last axiom says that, if we strictly prefer some act f to some other act g , conditionally to some event E and whatever the consequence $g(s)$ the act g yields in E , then we should strictly prefer act f to act g conditionally to event E . Formally,

P7 (conditional dominance)

For every event E and all acts f and f' , if $f >_E g(s)$ for all s in E , then $f >_E g$.

Under *P1–P7*, Savage’s second main theorem proves that the individual should maximize the expectation of a utility function, namely, a real-valued function defined on the set of consequences, with respect to the *unique* probability measure established as a result of *P1–P6* (see above). The utility function is unique up to a positive affine transformation and bounded. Formally, for all acts f and g

$$f \succeq g \iff \int_S u[f(s)] dp(s) \succeq \int_S u[g(s)] dp(s) \quad (11)$$

A consequence of Savage’s results is that the distinction between risk and uncertainty loses its meaning very much under *P1–P6*. Yet, the framework described above is quite complex. This is why Anscombe and Aumann provided us with a different setting, leading to a less complex treatment [5].

Anscombe and Aumann’s Contribution

Here we follow the notations of the section titled “Early Contributions” unless otherwise stated. Anscombe and Aumann [5] distinguish between “horse lotteries” (h-lotteries), which correspond to a case of uncertainty, and “roulette lotteries” (r-lotteries), which correspond to risky situations. Under their representation, the amounts at stake when betting on horses are not money prizes, but rather tickets to some r-lotteries. Thus, an act in the Savagian sense above is here a function from S (set of states of the world) into the set of r-lotteries, say L . Note that S is a finite set here. Subjective probabilities of h-lotteries will then result from observed choices’ comparisons between lotteries that are compounded from h- and r-lotteries. To ease matters, the axiom Anscombe and Aumann iron out is their “reversal of order in compound lotteries”, which is akin to the vNM “mixture

space” hypothesis *extended to h-lotteries*. We may therefore mix two acts f and g as we have mixed above two vNM lotteries (here: r-lotteries), i.e., $\alpha f + (1 - \alpha)g \in F$, with the definition that, whatever the possible outcomes $f(s)$ and $g(s)$, $[\alpha f + (1 - \alpha)g](s) = \alpha f(s) + (1 - \alpha)g(s)$. F is therefore convex and we essentially return to the kind of question solved by vNM. Aumann and Anscombe considerably simplify Savage’s framework, but at substantial expense.

Discussion and Conclusion

Many readers may find that the mathematical apparel necessary to define subjective probabilities as resulting from observed (real or experimental) bets is very heavy. This follows from the fact that the authors above want their base axioms to (a) make no reference to any of the collective links (institutional, psychosociological, etc.) between individual’s rationalities and (b) bear on sets of acts, states of the world and consequences, all endowed with the lightest possible structure, as in Savage, so that general conclusions may ensue. The second aspect is the source of an endless quest of mathematical psychology research; the first has been less dealt with by social mathematics research [3, 15, 16]. It allows less restrictive assumptions on individual rationality. Perhaps the continuity postulate $P6$ should be softened or perhaps even dispensed with, the present form being quite extreme [17].

The criticism of $P3$ and $P4$ with respect to state-dependent preferences has been alluded to in the text above. The sure thing principle and the independence axiom have been heavily criticized, notably in the experimental literature, with the result that alternative utility and decision models have been suggested. The impact of these generalizations on the very question of subjective probability is only beginning to be understood.

BERTRAND R. MUNIER

Subjective Probability

The fundamental reality that motivates interest in any form of probability is variability. There is variability over instances, space, and time. As a consequence, uncertainty is experienced: a lack of surety in the face of variability. Although uncertain, it is intuitively recognized that some things are more uncertain than others and variability itself is variable. That uncertainty has degrees also supports the attempts at its measurement. Thus, the overarching definition of subjective probability is that it is a measure that captures a degree of belief, a degree of judged certainty. Surrounding this general notion are several major variant approaches to subjective probability.

The first approach is to treat subjective probabilities as an interpretation of mathematical probability theory. Thus, the section titled “Subjective Probability as an Interpretation of Mathematical Probability Theory” of this article will begin with probability theory as a mathematical system and derive subjective probability as an interpretation of a correspondence between this theory and reality. Subjective probabilities, being personal, need to come from the person. There are two general variants for assessing these degrees of belief: the direct expression of likelihoods and the inference of likelihoods from expressed preferences. The section titled “Subjective Probabilities as Assessed Degrees of Belief” derives these variants from an axiomatic system for a qualitative probability structure designed to connect probability more directly to the underlying behavior it is intended to represent. In the section titled “Probabilities as Inherently Subjective” a broader argument is presented as a second general approach to subjective probability. The claim is that subjective probability is not just one of many interpretations, but, rather, subjectivity is an inherent aspect of all uses of probability, i.e. all probability statements are subjective. Bayesian inference is described as an outgrowth of this approach (*see* **Bayesian Statistics in Quantitative Risk Assessment**). The section titled “Justification-Based Measures of Subjective Probability” describes a third general approach to subjective probability, one that disconnects from traditional mathematical probability theory. Treated as a measure of a degree of belief or of subjective uncertainty, it is noted that uncertainty has not always been seen as a unitary construct. Specifically, from the early

days of probability theory, a distinction has been claimed between uncertainty arising from the weight of evidence and uncertainty arising from the balance of evidence. Dempster–Shafer degrees of belief are outlined to exemplify meaningful measures of uncertainty that are distinct from probability theory.

A good resource for many of the topics and issues raised in this article is the book edited by Wright and Ayton [1]. The book provides a good next step for those interested in pursuing subjective probabilities further.

Subjective Probability as an Interpretation of Mathematical Probability Theory

Mathematical Probability Theory

Probability theory is mathematical. Like all branches of mathematics, e.g., algebra or geometry, the theory is an abstract, self-contained representation, with no necessary connection to the reality in which we live. However, although this theory can be viewed separately from reality, like other mathematical theories, probability theory derives its strength and interest from its correspondence to reality that can be formed. In that we can draw a parallel between elements of geometry (points, lines, and planes) and elements of the real world (objects, edges, and surfaces), geometry is critical to good architecture and construction. Before addressing the correspondences for probability theory, the theory itself needs to be outlined.

As a mathematical theory, probability theory starts with basic principles and definitions and, from these, other laws and theorems are derived. Kolmogorov [2] is generally credited with the mathematical formulation of modern probability theory. He defined the field of probability as a system of sets and an assignment of numbers that satisfy the following axioms:

1. E is a collection of all elementary events [the complete set of possibilities].
2. All subsets of E , and their sums $[A + B]$, i.e., A or B , products $[AB]$, i.e., A and B and differences $[A - B]$, i.e., A but not B are defined.
3. Each subset A can be assigned a probability $P(A) \geq 0$. [Sets the lower bound at 0, which gets assigned to the impossible event.]
4. $P(E) = 1$. [Sets the upper bound at 1; that one of the elementary events will occur is presumed certain.]

5. If A and B are mutually exclusive (have no elementary events in common), then $P(A + B) = P(A) + P(B)$.

These axioms, along with the definitions of a conditional probability [probability of A given B , i.e., conditional on the assumption that B occurs for certain]:

$$P(A | B) = \frac{P(AB)}{P(B)} \quad (1)$$

and of independent events:

A , B are independent if $P(AB) = P(A) \times P(B)$

are the key specifications of mathematical probability theory.

Views of Theory Correspondence

How then to apply this theory in the real world? First two nonsubjective interpretations of probability are presented to provide the context for a third, subjective view that is the focus of this article.

Classical View. *What is the probability of a coin turning up heads in a single toss?*

In the history of probability theory (e.g., as described by Hacking [3]), games of chance provided an early motivation for the theory's development. The view begins with the specification of the elementary events of Axiom 1. Further, the situation provides no differentiating knowledge about the elementary events, and a perceived symmetry is observed among them. For example, the usual six-sided die provides no information as to any side being favored, and each side is roughly equivalent. This state of affairs leads to an application of the principle of insufficient reason, whereby all elementary events are accorded the same likelihood (for the die, each face has probability $1/6$ of appearing).

This view has been most usefully applied in using probability as the metric for games of chance, e.g., in casinos and lotteries. Under this interpretation, the emphasis is upon counting: translating the numbers of elementary events to numbers of more complex events using the relationships derived within mathematical probability theory. For example, if drawing each individual card in a standard deck of 52 cards is an elementary event having a $1/52$ chance, what

is the probability of getting exactly three matching card values out of five cards (a three-of-a-kind)? The mathematics of probability theory combines with that of combinatorics to derive complex probability statements like these.

Frequentist View. *What proportion of days in the past 10 years has there been a traffic accident involving at least one fatality, within the city limits of Minneapolis, Minnesota (USA)?*

What is the probability of a traffic accident involving at least one fatality tomorrow, within the city limits of Minneapolis, Minnesota (USA)?

Probability is also recognized as describing proportions, as in the first traffic example above. Proportions clearly correspond with the tenets of probability theory; indeed, probability theory is well characterized as the mathematics of proportions. So, the proportion of days with exactly one fatality can be added to the proportion of days with two or more fatalities and this sum will exactly equal the proportion of days with one or more fatalities (an application of Axiom 5).

The frequentist interpretation takes this correspondence and extends it to the realm of uncertainty. As a measure of likelihood, the frequentist interpretation views probabilities as idealized proportions (as the number of observations approaches infinity). Thus, the proportion of the first traffic example could be idealized to a representation of a process producing potentially indefinite traffic fatality values over time, according to some idealized proportion. To the extent that tomorrow's value is drawn from this process, the idealized proportion provides a likelihood estimate for tomorrow. Reversing the logic, as the number of tomorrows increases (approaching the unreachable, idealized value of infinity), the observed proportion of days with fatalities converges to a value that is then accepted as the probability.

In general, this view is treated as useful in situations where there is (a) repeatability (identical events are recurring so that some large number of occasions can be observed) and (b) stability (the same process is operating over time to generate these occasions, so that the events are identically distributed). Unlike the classical view, the elementary events are not assumed to be equally likely. However, they could be, making this interpretation a more general case of the classical view, with an empirical grounding.

Subjective View. *What is the probability of the euro being adopted by the United Kingdom within the next 10 years?*

It is hard to imagine any set of similar, equivalent events for which a frequentist interpretation of this probability would make sense. And yet, making such a judgment does make sense to most people. The subjective view partly arose from such considerations.

In the subjective view, probabilities are characterized as degrees of belief, more specifically as judged likelihoods. Probabilities under this interpretation are presumed to derive from the evidence that underlies the qualified belief. This evidence could include the presumption of equal likelihoods or evidence of proportions, making this interpretation a more general case of the classical and frequentist views, while stepping back from the more direct empiricism of the frequentist view.

Thus, one approach to subjective probability is as an interpretation of the mathematical theory of probability. In this approach, a subjective probability is a correspondence between the theory and a reality defined as a subjective degree of belief based on evidence. Before turning in the section titled “Subjective Probabilities as Assessed Degrees of Belief” to the development of two variants of this correspondence, the next section discusses the implications of this view for the important issue in risk assessment of the quality of subjective probability measures.

Quality: Internal Coherence

Under this perspective, what does it mean for a subjective probability to be good or at least better than another? What standard of quality can be meaningfully applied? One difficulty with the subjective view as a generalization of the frequentist view, as described above, is the disconnect that is created from empirical evidence. Whereas frequentist probabilities can be meaningfully compared with observed proportions (e.g., see the section titled “Quality: Scoring Rules”), subjective probabilities do not necessarily afford such a comparison. If one person judges that the $P(\text{Rain tomorrow}) = 0.7$ based on the evidence he or she has and another person judges $P(\text{Rain tomorrow}) = 0.6$ based on his or her evidence and if it rains tomorrow, is the former’s judgment better? Since the judgment is personal and based on different evidence, we might be hesitant

to draw this conclusion, particularly for unrepeatable events.

The primary means of assessing quality that has developed from the view of subjective probability as an interpretation of mathematical probability is the criterion of internal coherence. This criterion is not applicable to a single judgment like the above; no quality assessment of a single subjective probability has been convincingly argued. Internal coherence does provide a quality standard for certain groups of judgments, however. The mathematical theory, e.g., as illustrated by Axiom 5 and by the definition of conditional probability (equation (1)), makes statements about how probabilities are related to each other. So, if independent assessments of $P(A)$, $P(B)$, and $P(A + B)$ are made for events A and B that are disjoint, then they should relate to each other according to the specifications of Axiom 5: $P(A) + P(B) = P(A + B)$. For subjective probabilities to satisfy this condition represents internal coherence. The three probabilities cohere as a group to the required relationship set forth by the mathematical theory.

Numerous studies have tested different relationships required by the theory. Generally, the results are not positive; subjective probabilities typically do not cohere. For the relationship in Axiom 5, individuals tend to be superadditive, underjudging the likelihood of a disjunction, i.e., stating judgments such that $P(A) + P(B) > P(A + B)$ for mutually exclusive events A and B . For example, Barclay and Beach [4] asked students to imagine someone they know getting a car for graduation. They assessed the probabilities of the car being a Ford, being a Chevrolet, and being a Ford or a Chevrolet. The average responses showed $P(\text{Ford}) + P(\text{Chevrolet}) > P(\text{Ford or Chevrolet})$. A special case of the effect is for partitions of the collection of all possibilities: $\{A_i\} = E$. Wright and Walley [5] showed partitions having five to six constituent elements to have a probability sum of about 2 (vs $P(E) = 1$); and, for partitions of 16 elements, the sum rose to 3.

One of the earliest lines of research (e.g. [6]) on the coherence of subjective probability judgments demonstrated conservatism in the updating of probabilities with evidence, as compared to Bayes’ theorem (see **Bayes’ Theorem and Updating of Belief**). The theorem, which can be derived from the definition of a conditional probability given in equation (1), can

be stated as

$$P(H|D) = \frac{P(H)P(D|H)}{P(D)} \quad (2)$$

where H is interpreted as some hypothesis and D as data relevant to the hypothesis. In this equation, $P(H)$ is the prior probability of the hypothesis before the data are received and $P(H|D)$ is the posterior probability after the data are received. $P(D|H)$ expresses the likelihood of the data for this hypothesis and $P(D)$ normalizes the calculation so that the posterior probability remains within the interval $[0, 1]$. The usual finding was that judgments of $P(H|D)$ were less than those calculated using equation (2) from the judgments of the components on the right-hand side of the equation, i.e., the updated probability is too conservative.

An even more dramatic example of a failure of internal incoherence is the conjunction fallacy identified by Tversky and Kahneman [7]. The mathematical theorem tested in this case is that

$$P(AB) \leq P(A) \quad (3)$$

i.e., the joint occurrence of two events cannot be more likely than either event alone. For example, a head on the first toss of a coin cannot be less likely than a head on both of the first two tosses. As intuitive as this principle appears, systematic violations of the relationship have been demonstrated in a number of studies. The Linda problem, one of those used by Tversky and Kahneman, provides an oft-cited example. Consider the following description:

Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in antinuclear demonstrations.

Then, presented with several statements including the following that

- [A] Linda is a bank teller
- [B] Linda is active in the feminist movement
- [AB] Linda is a bank teller and is active in the feminist movement

the vast majority of respondents judged the likelihood of A as less than the likelihood of AB .

(For additional information, including reasons for such behavior, Yates [8] has an accessible discussion

of findings with respect to the internal coherence standard.)

Subjective Probabilities as Assessed Degrees of Belief

The mathematical approach of the previous section is outcome oriented. It focuses upon the resulting probabilities attached to events without considering how the degrees of belief arise. Addressing the latter leads to a more behaviorally oriented approach. There are two general means by which degrees of belief are obtained: by direct assessment of likelihoods and by inference from assessed preferences. And, an important theoretical foundation in either case is the use of an axiomatic theory that analyzes the conditions required of these assessments to derive probabilities from them. This section describes an axiomatic system for a qualitative probability structure designed to connect subjective probability more directly to the underlying behavior it is intended to represent.

Qualitative Probability Structures

In terms of an axiomatic subjective theory, de Finetti [9] provided the starting point. The idea is to provide minimal constraints on the judgments that would be used in assessing the probabilities and from which a coherent set of quantitative probabilities will be derived. In other words, if I want to have a set of numerical probabilities that behave in a coherent mathematical way, what constraints must be placed on the judgments? In the axiom system, the judgment is described as a qualitative comparative relation, $A \succsim B$, between sets (events) A and B . Typically, this relation translates to either “is at least as likely as” or “is at least as preferred as”. These two interpretations form the bases of the next two subsections. The axiomatic structure below follows that described by Luce and Suppes [10].

1. All subsets of E , and their sums $[A + B$, i.e., A or $B]$, products $[AB$, i.e., A and $B]$ and differences $[A - B$, i.e., A but not $B]$ are defined [equivalent to Axiom 2 above for mathematical probability theory].
2. $A \succsim B$ and $B \succsim C$ implies $A \succsim C$ [transitivity].
3. Either $A \succsim B$ or $B \succsim A$ [or both; 2 and 3 signify that there is a weak ordering of all subsets, “weak” in that ties are allowed].

4. If A and C are mutually exclusive (have nothing in common) and B and C are mutually exclusive, then $A \succeq B$ if and only if $A + C \succeq B + C$ [common elements, e.g., C , can be ignored or included without effect, a principle of the irrelevance of common alternatives].
5. $A \succeq \emptyset$ [i.e., nothing is less likely than the impossible event; sets a lower bound].
6. Not $\emptyset \succeq E$ [the entire set of possibilities is more likely than the impossible event; eliminates the trivial case in which everything is impossible].

To these axioms we can add the following definition:

$A \succ B$ if and only if $B \not\succeq A$,

defining the strict ordering relation (without ties). A conditional probability can also be defined; however, this is more complicated and will be left aside here. Suppes and Zanotti [11] provide an example. For our purposes, it is sufficient to note that constraints on relations involving conditionality are similar to those above, and support the existence of a quantitative definition like that of equation (1).

The qualitative axioms present a series of constraints on subjective probability judgments. For example, Axiom 2 claims transitivity: If rain tomorrow is judged to be at least as likely as snow and snow is at least as likely as fair weather, then the axioms require that rain be judged to be at least as likely as fair weather. As straightforward as transitivity seems, there are situations for which preferences have been demonstrated to violate transitivity [12]. Such behavior presents a caution to derivations of subjective probability.

In terms of these axioms, probably the most controversial is Axiom 4. As an example, Ellsberg [13], in introducing the concept of ambiguity and positing consistent ambiguity aversion, focused on this axiom. The challenge can be demonstrated by the following

example (Table 1). An urn contains 150 balls: 50 of these are known to be blue and the remaining 100 are red and/or white in some unknown proportion. All 100 could be red, white, or anything in between. Several options, A–D, are defined with respect to this urn with the payoffs associated with color draws in each game shown by Table 1.

Two choices are offered: a choice between option A and option B and a choice between option C and option D. In the first choice, the modal selection is option A, avoiding the additional uncertainty, termed *ambiguity*, of option B. (How many winning balls are there?) In the second choice, the modal selection is option D, similarly avoiding the ambiguity of option C. However, this pattern of choices is inconsistent with a qualitative probability structure, particularly with Axiom 4, the irrelevance of common alternatives.

To show this, we can set the utility or value $u(\$100) = 1$ and $u(\$0) = 0$, since value is generally recognized as being scaled intervally, i.e., any linear transformation of value retains its meaning. Then, the preference for option A implies

$$P(\text{Blue}) > P(\text{Red})$$

whereas the preference for option C implies

$$P(\text{Red}) + P(\text{White}) > P(\text{Blue}) + P(\text{White})$$

or, canceling the common alternatives

$$P(\text{Red}) > P(\text{Blue})$$

leading to incompatible inequalities.

The problem highlighted by this particular example leads to an expansion of the concept of subjective probability that is taken up in the section titled “Justification-Based Measures of Subjective Probability”. In addition, the example shows a potential discrepancy between two forms of assessing subjective probabilities. These are identified next.

Assessing Subjective Probabilities

By far, the most common way of assessing subjective probabilities in practice is to do so directly. The relation $A \succeq B$ is generally interpreted as “ A is at least as likely as B ”. By this method, degrees of belief as sensitive to likelihood are taken as the primitives that assessors can judge directly. Thus, a weather forecaster or a physician, providing a forecast or diagnosis, directly reports the numerical measures. As demonstrated by the example in the previous section,

Table 1 Sample options demonstrating a version of Ellsberg’s paradox

Option	50 balls		100 balls
	Blue	Red	White
A	\$100	\$0	\$0
B	\$0	\$100	\$0
C	\$100	\$0	\$100
D	\$0	\$100	\$100

an alternative is to derive subjective probabilities from preferences. In this case, the relation $A \succeq B$ is generally interpreted as “A is at least as preferred as B”.

Decision scientists have tended to favor this latter approach, grounded on preference behavior. Savage’s [14] landmark treatise particularly connected probability and utility theory, providing a theoretical and axiomatic basis for what has come to be known as *subjective expected utility (SEU) theory*. This theory incorporates a subjective (personal) probability measure into preference as modeled by utility theory. Another manifestation of the decision analytic ties between probability and utility is the probability elicitation method for assessing utilities. In this method, utilities are derived from judgments like the following: for what probability P are you indifferent between receiving \$50 for certain; or, receiving \$100 with probability P , otherwise receiving nothing? This method essentially measures utilities as an assessment of preference along a probability scale.

Under a strict decision analytic view (*see Decision Analysis*), judgments are only of significance if they are connected to consequences. Direct assessments that are not grounded in outcomes do not qualify. Only preference-based methods, tied to real outcomes, lead to usable subjective probability assessments. Despite this argument, in practice, direct assessments predominate.

Quality: Convergence

Considering subjective probabilities as arising from an assessor based on the evidence available, another view of decision quality can be proposed. However, for whatever reasons, this approach is rarely used. From this view, quality can be defined as correspondence with a converging value with shared evidence. This idea has at least three components. First is that multiple judges of an event will tend to converge on a common probability judgment as they increasingly share their knowledge on which the judgment is based. Second is that, if two judgments are based on sets of information where one set of information is a subset of the other, then the judgment based on the more inclusive set of evidence is not worse than the other. Third is that quality can be measured as the degree of correspondence with the convergent value under the condition that the shared information is complete, i.e., as the information is fully shared. This

notion of quality is more speculative than the others identified in this article, as this view has not been applied experimentally to the evaluation of subjective probabilities. However, authors have identified convergence as a potential expectation and, as such, it provides a potential standard of quality.

Probabilities as Inherently Subjective

All the above characteristics define subjective probability as against other means of interpreting probability, e.g., against classical or frequentist interpretations. An alternative approach is to accept that probabilities in practice are all subjective. The characteristics that lead to the interpretations are just different forms of evidence.

Consider rolling a six-sided die. The probability of a single roll leading to an ace is generally judged to be 1/6. Such an assessment, from the classical view, arises from there being six elemental events, each of which is treated as equally likely. But, how does one determine that they are equally likely? Not all elemental events are so. If one is assessing the $P(\text{Rain in Minneapolis MN, USA, tomorrow})$, one can define Rain and Not Rain as elemental events, but they are not equally likely. To define equally likely events in this situation is probably not possible (a limitation of the classical view that led to its falling from favor). So, again, how does one determine that the six outcomes of a die roll are equally likely? One cannot prove this logically. One cannot prove this empirically either. Even under the frequentist view of a probability as a long-run frequency, the long run is not an empirical possibility but a theoretical concept: the frequency as the number of rolls approaches an unattainable infinite number of rolls.

Finally, the answer is that one cannot prove that the events are equally likely. Ultimately it is a subjective assessment. Consequently, the principle of insufficient reason is understood, not as a statement of how to treat symmetrical events but, as a subjective recommendation of how to assign probabilities to elemental events when no other evidence is available.

Similarly, probability is not equivalent to frequency, even in an idealized sense. To the extent that frequencies underlie a probability, wholly or in part, this also is ultimately a subjective judgment arising from the assessor’s knowledge. If it is just analyzing how proportions are related to each other, no

subjective assessment is necessary. But, the use of proportions as a basis for a probability is necessarily going beyond the available evidence to treat the proportion as an idealized long-run frequency. What justifies such a statement? The frequentist interpretation of probability is argued here as grounded in subjective assessments of repeatability and stability. Consider assessing the likelihood of a traffic fatality in Minneapolis tomorrow by using past frequency data. It is assumed that the events underlying the proportion are comparable to each other (e.g., each day is comparable to an identifiable set of other days) and that the likelihood is unchanging (e.g., the chances of an accident tomorrow are the same as on each of those other comparable days). How can we know either of these conditions? We cannot. It is a subjective assessment based on available evidence that leads us to operate on these assumptions.

The argument, therefore, is that subjective probability is not one of several possible interpretations of probability, but rather that all real-world applications of the mathematical probability are necessarily subjective. Elaborating, the uncertainty being captured in a probability judgment is recognized as depending not only on the event being assessed, but also necessarily upon the knowledge that the assessor brings to the judgment.

Bayesian Inference

The recognition of a subjective aspect in using any probability extends to the use of probabilities in statistical inference, most notably in the Bayesian approach to inference (see **Bayesian Statistics in Quantitative Risk Assessment**). Traditional statistical inference, as manifest in null hypothesis testing and the use of p values is frequentist. A p value is interpreted as the probability of a sample result, in an idealized long-run number of experiments, if the null hypothesis is true. In this, the p value is most comparable to the likelihood in equation (2), $P(D|H)$, with a frequentist interpretation of this probability.

The Bayesian inference approach considers inference from a more subjective viewpoint. The approach is to consider probability statements as arising from the consideration of evidence, from a process of updating assessments based on accumulating evidence. Bayes' theorem, which describes the updating of an hypothesis in light of data, for example as

expressed in equation (2), is the conceptual centerpiece to the subjective approach to statistical inference. First, the focus is upon $P(H|D)$ rather than $P(D|H)$. Congruently, the interpretation of the posterior $P(H|D)$ is as a subjective degree of belief in light of the evidence of D .

As to the first point, the Bayesian approach is accommodating a more natural way of viewing the situation. Anyone who has taught an introductory statistics course can testify to the nonintuitive nature of the p value as $P(D|H)$. Despite all warnings to the contrary, students tend to treat the p value as $P(H|D)$. This confusion of the two conditionals has also been observed notably by Eddy [15] in his analysis of reports in the medical literature. Eddy observed the same tendency among researchers interpreting medical data as observed in the introductory class, interpreting $P(D|H)$ as $P(H|D)$. Bayes' theorem explicitly acknowledges that it is ultimately $P(H|D)$ that is of interest and models this explicitly.

The second complementary aspect is the interpretation of the resulting probability, the posterior $P(H|D)$, as subjective. In particular, the probability is interpreted as a degree of belief in response to evidence. In this light, the principle of insufficient reason of the classical view is simply a proposal for the starting point, the prior probability $P(H)$ before any evidence is available. And, frequencies are just a particular form of evidence D from which posterior probabilities are derived, along with any other non-frequentist evidence that may be available. In the end, all probabilities are viewed as subjective statements based on evidence.

Quality: Scoring Rules

Subjective probability as an encompassing category, treating all probabilities as inherently subjective, creates a connection back to the frequentist approach that has been exploited in evaluating the quality of subjective probability assessments. The approach removes the distinction between subjective and frequentist probabilities, treating frequencies or base rates, as just part of the information that can be incorporated subjectively. Thus, this evidence also can be used to evaluate subjective probabilities without contradiction.

The most direct applications of this idea are calibration analyses. A subjective probability judgment of 0.70 attached to some target event is said to be

well calibrated if the target event occurs 70% of the time that such a probability is stated. If this is true for all the probability numbers that one uses, then he or she is a well-calibrated judge. The usual index used to measure calibration is the weighted squared differences between the actual frequencies and the subjective probability judgments.

Typically, researchers try to select events, in the calculation of the calibration index, that are comparable, i.e., that can arguably be classified as repeatable events of the same type. In different situations though, this comparability may be closer than in others. In weather forecasting, for example, each daily forecast can be considered a repeatable event, forming a reasonably coherent category of events. Alternatively, researchers have requested probability assessments using general knowledge questions on a variety of topics (How certain are you that your answer is correct?), a less coherent set of events.

This variability in the use of calibration has not gone unnoticed. Most notably, Gigerenzer *et al.* [16] made a similar point in questioning the ecological validity of questions used in calibration studies, i.e., challenging to what extent the distribution of questions reflects what is encountered in everyday life. Here, the somewhat curious aspect of using frequentist data to evaluate subjective probabilities is simply observed. From a view where these are distinct interpretations of mathematical probability, this is nonsensical; however, the rationale is supported by a view that encompasses all probability interpretations within the subjective rubric.

Expanding off of this idea, calibration is just one aspect of performance that can be assessed by comparing judgments to observed frequencies. Other measures can be identified beginning with the idea of scoring rules. The most common scoring rule used is the quadratic rule. Defining p_j as the subjective probability for situation j and d_j as an outcome index such that

$$d_j = 1 \text{ if the target event being assessed occurs} \\ 0 \text{ if the target event does not occur}$$

the quadratic rule is an overall index given by

$$\sum_j (p_j - d_j)^2 \quad (4)$$

The quadratic rule is a proper scoring rule. A *proper* scoring rule is one that, if used to reward performance, leads to maximal payoff when assessors report their judgments honestly and accurately without bias. Another reason for the widespread use of the quadratic rule is the ability to decompose the overall score into component scores that are diagnostic of different aspects of performance quality, including the calibration index discussed above. Yates [17] provides a good discussion of properness – demonstrating the property with several rules, proper and improper – and of scoring rule decompositions of the quadratic rule.

Justification-Based Measures of Subjective Probability

In the earlier sections, there was a progression of generality from considering subjective probability as one interpretation among several of the mathematical theory of probability to considering subjective probability as encompassing all behavioral applications of probability. In this section, the generality is pushed further to consider subjective probability as a general approach to uncertainty whether grounded in the traditional mathematical theory of probability or not. Two basic variations can be identified.

The first uses measures that allow imprecision in the subjective probability judgments. Instead of requiring a precise judgment, however assessed, some vagueness is allowed. Examples are uses of upper/lower probabilities, so that individuals need to only specify a range of values. Similar in spirit, though even less precise, are uses of verbal phrases of likelihood, e.g., “possibly”, “probably”, or “high chance”.

The second variation of measuring uncertainty, outside of mathematical probability theory, is as old as probability theory itself, tracing to the earliest days of the development of the mathematical theory. The basic idea is that there are two clearly distinguishable aspects of uncertainty that have subjective correlates, each of which can be, and has been, expressed as a degree of belief, though distinct. Following the evidential approach of the previous section, the two relate to the strength of evidence and the weight of evidence that underlie the subjective assessment. Alternatively, if knowledge is classified as justified true belief (e.g. [18]), then there are two criteria

implied. Subjective probabilities as likelihoods capture the degree of belief relative to the criterion of truth; but, subjective probabilities could equally be developed relative to the criterion of justification. Shafer [19] provides an excellent, comprehensive history of the difference.

The distinction is well demonstrated by the concept of ambiguity as described and illustrated by Ellsberg [13]. Reconsider options A–D in Table 1 involving the urn containing 150 balls: 50 blue and 100 red and/or white balls in an unknown proportion. As posited by Ellsberg, people will react to the ambiguity in the choices between options A and B and between options C and D. The behavior is typically one of avoiding ambiguity and reactions to ambiguity have been widely verified (e.g. [20–22]). The example exemplifies two types of uncertainty. Relative to the truth criterion, all the options involve risk in that the outcome (the true state of affairs that will occur), \$100 or nothing, is uncertain. If asked for the likelihood of winning, the modal response is consistent: 1/3 for options A and B and 2/3 for options C and D. These likelihoods capture the balance of the evidence. There being no additional evidence, the balance of the evidence falls equally toward the three elemental events of the three colors, i.e., $P(\text{Each color being drawn}) = 1/3$. Options B and C, however, also contain additional uncertainty, termed *ambiguity* by Ellsberg, in that the chances of winning are more uncertain for these options. Relative to the justification criterion, the difference is in the weight of the evidence with these options. There is more information about options A and D, more justification or support for conclusions drawn about them, as the exact proportions of winning and losing colors are known. The justification is less for options B and C.

The goal of incorporating weight of evidence into a subjective measure of uncertainty motivates the development of a number of calculi as alternatives to standard mathematical theory of probability as outlined above, e.g., the use of certainty factors or possibilistic measures, particularly in artificial intelligence [23, 24]. As an example, consider the functions within Dempster–Shafer theory as measures of support. A full account of the rationale and mathematical formulation can be found in Shafer [25]. An operationalization of the theory as a subjective probability measure using direct assessments was done by Curley [26] in a study of the evaluation of evidence in a

legal setting. In traditional, direct probability assessment, numbers are assigned to a partition of the set of all possibilities (S) such that the numbers sum to 1. Alternatively, reserve functions allow judges to assign numbers to any subset of S so that they sum to 1. Assigning $m\%$ of one’s belief to a subset is interpreted as follows: “On the basis of the evidence, I believe with $m\%$ of my belief that the possibilities in this set are supported; however, I cannot distinguish between the elements in the set individually.” When there is no evidence, all the belief is reserved to S , $m(S) = 1$. As evidence accumulates, the evidence moves into subsets to the degree that the evidence implicates the contained elements.

For example, suppose a piece of evidence implicates a left-handed suspect and persons A and B among the possible suspects are left handed. Initially, before any evidence is available, $S = \text{set of possible suspects}$ and $m(S) = 1$. With the piece of evidence implicating persons A and B, the support moves so that $m(\{A, B\}) = k$ and $m(S) = (1 - k)$, where k is the degree of implication provided by the evidence. This creates two differences from probability theory. First, with traditional probability if the likelihood of $\{A, B\}$ following this evidence is P , then the likelihood of all other suspects excluding $\{A, B\}$ is $(1 - P)$. This is not the case with justification (as S includes all suspects, including A and B), and the mathematics of reserve functions does not force this requirement. Second, in probability theory, for A and B distinct, $P(\{A, B\}) = P(\{A\}) + P(\{B\})$: in considering which is true, the likelihood of A or B is the sum of their relative likelihoods. In considering which is justified, this is not required. In the above example, $m(\{A\}) = m(\{B\}) = 0$, while $m(\{A, B\}) = k$. A support function does not require that the justification be able to be partitioned into the constituent elements if the evidence does not support doing so.

Being more novel and less used, the approaches in this section have not addressed the issue of quality. Ultimately, internal coherence (*cf.* the section titled “Quality: Internal Coherence”) and convergence (*cf.* the section titled “Quality: Convergence”) criteria seem most promising.

Conclusion

Subjective probability, generally characterized as a degree of belief in the face of uncertainty arising from

variability in our environment, has proven a robust construct. Several major variant approaches to subjective probability have developed. One view frames subjective probability as one of several interpretations whereby the mathematical theory of probability can be applied in real life. The probabilities are either assessed directly or inferred from stated preferences. Alternatively, it is argued that all probabilities are subjective, derived from evidence which may include frequency or process information. Bayesian inference best connects to this view. Finally, alternatives to the mathematical theory of probability have been proposed. Degrees of belief, as capturing the justification provided by evidence as opposed to the likelihood of the resulting events occurring, are described as an exemplar.

Supra Decision Maker

Decisions about the regulation of risks typically impact on a number of different sectors of society, and so have to take cognizance of the views of a variety of parties. In a system of representative democracy, such decisions often fall within the remit of independent regulators or agencies, for example, an Environment Agency. In the case of particularly consequential decisions, such as the disposal of nuclear waste, governments may retain decision making authority centrally, but may request a broadly based *ad hoc* committee to study the alternatives, and make the decision on the basis of the committee's recommendations (see **Stakeholder Participation in Risk Management Decision Making**).

One way to conceptualize such decisions is to think of the parties who are impacted by the decision – the “stakeholders” – as having preferences which are representable by value functions $v_i(\cdot)$ over an alternative space X (where i indexes n stakeholders). In this case, we can think of the regulatory or governmental decision maker as a “supra decision maker” (supra DM), who wishes to take account of the various $v_i(\cdot)$ in their own value function $V(\cdot)$.

Essentially, the supra DM concept is a way of thinking about the aggregation of individual preferences, a topic that has been explored extensively in the social choice, welfare economics and game theory literatures. However, the notion of a “supra DM” represents a distinctively decision-theoretic take on this topic, turning the focus on concrete choices made by an actual agent, rather than seeking to characterize properties of particular aggregation rules in the abstract.

As an example of how this perspective can be useful, consider the parallel problem of aggregating probability distributions elicited from a number of experts. An important question is: should it matter whether probabilities are updated *via* Bayes theorem (see **Bayes' Theorem and Updating of Belief**) with data before or subsequent to aggregation? As it happens, with popular approaches to aggregation such as linear opinion pools, it does matter (these aggregation procedures do not exhibit “external Bayesianity”). Here, the introduction of a (Bayesian) supra assessor, who takes as input data the probability distributions assessed by a number of individual assessors, has been used as a thought experiment to clarify

ideas about the desirability or otherwise of external Bayesianity [1].

Is it helpful to entertain the idea of an *expected utility maximizing supra DM* analogous to this Bayesian supra assessor? A compelling argument against this is provided by Broome [2]. The Sure Thing Principle of Utility Theory (see **Utility Function**) requires that if a supra DM is indifferent between two alternatives, she is also indifferent between these alternatives and their probabilistic mixture. Yet, in choosing which of the two indistinguishable individuals is to receive an indivisible good or bad (such as a green card or a Vietnam call-up), a supra DM might prefer to hold a lottery rather than make a deterministic allocation to one person or another.

Because this role for randomizing devices in the fair allocation of goods seems to undercut utility theory, the focus here, is only on the theory of the supra DM in the case of certainty. The formalization of this theory presented in Keeney and Raiffa [3, pp. 524–526] involves the following three assumptions: first, an assumption that the supra DM's preferences are completely determined by the stakeholders' preferences; secondly, an assumption of preferential independence on the part of the supra DM; and thirdly, a Pareto-like assumption that if an alternative can be unilaterally improved for one stakeholder, without worsening it for any of the other stakeholders, the improved alternative will be preferred by the supra DM.

Given these assumptions, it can be shown that the supra DM's value function must take the form $V(x) = \sum_{i=1}^n f_i(v_i(x))$. Further specialization of this function is possible: for example, the Bergson additive power form, $V(x) = \sum_{i=1}^n \alpha_i (v_i(x))^p$, has some attractive properties [4, Section 6]. The parameters of this function have a natural interpretation, as the multiplicand α_i is a person weight and the power parameter p reflects the supra DM's equity attitude, with $0 < p < 1$ corresponding to inequity aversion.

Yet this formal presentation avoids two crucial problems, which relate to the essentially private, personal nature of preferences. The first problem is the difficulty of knowing whether the stakeholders have reported their preferences honestly. Theorists in the field of social choice have agonized over this question, even before Gibbard [5] demonstrated that all voting systems of any interest encourage

strategic voting behavior. Devices for incentivizing the revelation of true preferences do exist, but are unlikely to be implementable in a risk analysis setting. Practically speaking, the supra DM's only recourse is to make a judgment about whether preference information is being given in good faith, and such judgments, inevitably, are fallible.

The second, more philosophically profound, problem arises from the impossibility of knowing with a high level of precision what it feels like to be someone else. Assessing the person's weights, α_i requires the supra DM to imagine *how strong her preferences for one alternative over another would be if she were stakeholder i* relative to *how strong her preferences would be for some other pair of alternatives if she were stakeholder i'* , where i and i' are distinct. (This leaves aside the further complicating possibility that the supra DM may care more strongly for one stakeholder than another.) Requiring both a high level of empathy with stakeholders and a facility in characterizing one's own internal states quantitatively, this is a remarkably demanding mental task to set for anyone.

Perhaps because of these problems, actual decision and risk analyses tend not to structure problems using the supra DM formulation, although some examples do exist (e.g. [6]). Instead, conflicts in values tend to be dealt with in other ways. For example, one approach is to collect decision criteria relevant to all stakeholders and evaluate alternatives on these criteria. Different systems of preferences can be explored by parameterizing the model with sets of criteria weights reflecting the value judgments of different stakeholders, as the UK's Committee on Radioactive Waste Management (CoRWM) did in their analysis of disposal options for the UK's radioactive waste [7]. This approach facilitates the identification of robust solutions and sheds light on why holistic preferences might differ.

The supra DM formulation may be particularly unhelpful in applications where active involvement is sought from stakeholders in the analysis. The reasons are not far to seek – the explicit representation of individual stakeholder preferences may lead to

positions hardening, and the starkness of the interpersonal trade-offs required of the supra DM seem unlikely to facilitate acceptance of whatever solution emerges from the process. Yet, many risk-related decisions *do* impact different stakeholders differently, however much analysts may want to evade this, and the idea of a supra DM is a useful frame for thinking about, and perhaps for private analysis of, such decisions.

Survival Analysis

In many studies, the main outcome is the time from a well-defined *time origin* to the occurrence of a particular event or *endpoint*. If the endpoint is the death of a patient, the resulting data are literally *survival times*. However, other endpoints are possible, for example, the time to relief of symptoms or to recurrence of a particular condition, or simply to the completion of an experimental task. Such observations are often referred to as *time to event data* although the generic term *survival data* is commonly used to indicate any time to event data.

Standard statistical methodology is not usually appropriate for survival data, for two main reasons:

1. The distribution of survival time, in general, is likely to be *positively skewed* and so assuming normality for an analysis (as done, for example, by a *t*-test or a regression) is probably not reasonable.
2. More critical than doubts about normality, however, is the presence of *censored* observations, where the survival time of an individual is referred to as *censored* when the endpoint of interest has not yet been reached (more precisely *right-censored*). For true survival times this might be because the data from a study are analyzed at a time point when some participants are still alive. Another reason for censored event times is that an individual might have been *lost to follow-up* for reasons unrelated to the event of interest, for example, due to moving to a location that cannot be traced. When censoring occurs, all that is known is that the actual, but unknown, survival time is larger than the censored survival time.

Specialized statistical techniques that have been developed to analyze such censored and possibly skewed outcomes are known as *survival analysis*. An important assumption made in standard survival analysis is that the censoring is *noninformative*, that is, the actual survival time of an individual is independent of any mechanism that causes that individual's survival time to be censored. For simplicity, this description also concentrates on techniques for continuous survival times; for the analysis of discrete survival times see [1, 2].

A Survival Data Example

As an example, consider the data in Table 1 that contain the times heroin addicts remained in a clinic for methadone maintenance treatment [3]. The study ($n = 238$) recorded the duration spent in the clinic, and whether the recorded time corresponds to the time the patient leaves the program or the end of the observation period (for reasons other than the patient deciding that the treatment is “complete”). In this study, the time of origin is the date on which the addicts first attended the methadone maintenance clinic and the endpoint is methadone treatment cessation (whether by patient's or doctor's choice). The durations of patients who were lost during the follow-up process are regarded as right-censored. The “status” variable in Table 1 takes the value unity if methadone treatment was stopped, and zero if the patient was lost to follow-up. In addition, a number of prognostic variables were recorded

1. one of two clinics
2. presence of a prison record
3. and maximum methadone dose prescribed.

The main aim of the study was to identify predictors of the length of the methadone maintenance period.

Survival Analysis Concepts

To describe survival, two functions of time are of central interest. The *survival function* $S(t)$ is defined as the probability that an individual's survival time, T , is greater than or equal to time t , that is,

$$S(t) = \text{Prob}(T \geq t) \quad (1)$$

The graph of $S(t)$ against t is known as the *survival curve*. The survival curve can be thought of as a particular way of displaying the frequency distribution of the event times, rather than by, say, a histogram.

In the analysis of survival data, it is often of some interest to assess which periods have the highest and which have the lowest chance of death (or whatever the event of interest happens to be), amongst those people at risk at the time. The appropriate quantity for such risks is the *hazard function*, $h(t)$, defined as the (scaled) probability that an individual experiences the event in a small time interval δt , given

Table 1 Durations of heroin addicts remaining in a methadone treatment program (only five patients from each clinic are shown)

Patient ID	Clinic	Status	Time (days)	Prison record 1 = present (0 = 'absent')	Maximum methadone (mg day ⁻¹)
1	1	1	428	0	50
2	1	1	275	1	55
3	1	1	262	0	55
4	1	1	183	0	30
5	1	1	259	1	65
...					
103	2	1	708	1	60
104	2	0	713	0	50
105	2	0	146	0	50
106	2	1	450	0	55
109	2	0	555	0	80
...					

that the individual has not experienced the event up to the beginning of the interval. The hazard function therefore represents the *instantaneous event rate* for an individual at risk at time t . It is a measure of how likely an individual is to experience an event as a function of the age of the individual. The hazard function may remain constant, increase or decrease with time, or take some more complex form. The hazard function of death in human beings, for example, has a “bath tub” shape. It is relatively high immediately after birth, declines rapidly in the early years, and then remains pretty much constant until beginning to rise during late middle age.

In formal, mathematical terms, the hazard function is defined as the following limiting value:

$$h(t) = \lim_{\delta t \rightarrow 0} \left[\frac{\text{Prob}(t \leq T < t + \delta t | T \geq t)}{\delta t} \right] \quad (2)$$

The conditional probability is expressed as a probability per unit time and therefore converted into a rate by dividing by the size of the time interval, δt .

A further function that features widely in survival analysis is the *integrated or cumulative hazard function*, $H(t)$, defined as

$$H(t) = \int_0^t h(u) du \quad (3)$$

The hazard function is mathematically related to the survivor functions. Hence, once a hazard function is specified so is the survivor function and *vice versa*.

Nonparametric Procedures

An initial step in the analysis of a set of survival data is the numerical or graphical description of the survival times. However, owing to the censoring this is not readily achieved using conventional descriptive methods such as box plots and summary statistics. Instead, survival data are conveniently summarized through estimates of the survivor or hazard function obtained from the sample.

When there are no censored observations in the sample of survival times, the survival function can be estimated by the *empirical survivor function*

$$\hat{S}(t) = \frac{\text{Number of individuals with event times} \geq t}{\text{Number of individuals in the data set}} \quad (4)$$

Since every subject is “alive” at the beginning of the study and no one is observed to survive longer than the largest of the observed survival times, then

$$\hat{S}(0) = 1 \text{ and } \hat{S}(t) = 0 \text{ for } t > t_{\max} \quad (5)$$

Furthermore, the estimated survivor function is assumed constant between two adjacent death times so that a plot of $\hat{S}(t)$ against t is a step function that decreases immediately after each “death”. However, this simple method cannot be used when there are censored observations since the method does not allow for information provided by an individual whose survival time is censored before time t to be used in the computing of the estimate at t .

The most commonly used method for estimating the survival function for survival data containing censored observations is the *Kaplan–Meier* or *product-limit-estimator* [4]. The essence of this approach is the use of a product of a series of conditional probabilities. This involves ordering the r sample event times from the smallest to the largest such that

$$t_{(1)} \leq t_{(2)} \leq \cdots \leq t_{(r)} \quad (6)$$

Then the survival curve is estimated from the formula

$$\hat{S}(t) = \prod_{j|t_{(j)} \leq t} \left(1 - \frac{d_j}{r_j}\right) \quad (7)$$

where r_j is the number of individuals at risk at $t_{(j)}$ and d_j is the number experiencing the event of interest at $t_{(j)}$ (individuals censored at $t_{(j)}$ are included in r_j). For example, the estimated survivor function at the second event time $t_{(2)}$ is equal to the estimated probability of not experiencing the event at time $t_{(1)}$ times the estimated probability, given that the individual is still at risk at time $t_{(2)}$, of not experiencing it at time $t_{(2)}$.

The Kaplan–Meier estimators of the survivor curves for the two methadone clinics are displayed in Figure 1. The survivor curves are step functions with decrease at the time points when patients ceased methadone treatment. The censored observations in

the data are indicated by the “cross” marks on the curves.

The variance of the Kaplan–Meier estimator of the survival curve can itself be estimated from *Greenwood’s formula* and once the standard error has been determined, pointwise symmetric confidence intervals can be found by assuming a normal distribution on the original scale or asymmetric intervals can be constructed after transforming $\hat{S}(t)$ to a value on the continuous scale; for details, see [1, 2].

A *Kaplan–Meier type estimator* of the hazard function is given by the proportion of individuals experiencing an event in an interval per unit time, given that they are at risk at the beginning of the interval, that is,

$$\tilde{h}(t) = \frac{d_j}{r_j (t_{(j+1)} - t_{(j)})} \quad (8)$$

Integration leads to the *Nelson–Aalen* or *Altshuler’s* estimator of the cumulative hazard function, $\tilde{H}(t)$, and employing the theoretical relationship between the survivor function and the cumulative hazard function to the Nelson–Aalen estimator of the survivor function. Finally, it needs to be noted that relevant functions can be estimated using the so-called *life table* or *actuarial estimator*. This approach is, however, sensitive to the choice of intervals used in its construction and therefore not generally recommended for continuous survival data (readers are referred to [1, 2]).

Figure 1 Kaplan–Meier survivor curves for the heroin addicts data

Standard errors and confidence intervals can be constructed for all three functions although the estimated hazard function is generally considered “too noisy” for practical use. The Nelson–Aalen estimator is typically used to describe the cumulative hazard function while the Kaplan–Meier estimator is used for the survival function.

Since the distribution of survival times tends to be positively skewed, the median is the preferred summary measure of location. The *median event time* is the time beyond which 50% of the individuals in the population under study are expected to “survive”, and, once the survivor function has been estimated by $\hat{S}(t)$, can be estimated by the smallest observed survival time, t_{50} , for which the value of the estimated survivor function is less than 0.5. The estimated median survival time can be read from the survival curve by finding the smallest value on the x axis for which the survival proportion reaches less than 0.5. Figure 1 shows that the median methadone treatment duration in clinic 1 group can be estimated as 428 days while an estimate is not available for clinic 2 since more than 50% of the patients continued treatment throughout the study period. A similar procedure can be used to estimate other percentiles of the distribution of the survival times and approximate confidence intervals can be found once the variance of the estimated percentile has been derived from the variance of the estimator of the survivor function.

In addition to comparing survivor functions graphically, a more formal statistical test for a group difference is often required. In the absence of censoring, a nonparametric test like the Mann–Whitney test could be used. In the presence of censoring, the *log-rank* or *Mantel–Haenszel test* [5] is the most commonly used nonparametric test. It tests the null hypothesis that the population survival functions $S_1(t), S_2(t), \dots, S_k(t)$ are the same in k groups.

Briefly, the test is based on computing the expected number of events for each observed event time in the data set, assuming that the chances of the event, given that subjects are at risk, are the same in the groups. The total number of expected events is then computed for each group by adding the expected number of events for each event time. The test finally compares the observed number of events in each group with the expected number of events using a χ^2 test with $k - 1$ degrees of freedom; see [1, 2].

The log-rank test statistic, X^2 , weights contributions from all failure times equally. Several alternative test statistics have been proposed that give differential weights to the failure times. For example, the *generalized Wilcoxon test* (or *Breslow test*) uses weights equal to the number at risk. For the heroin addicts data in Table 1 the log-rank test ($X^2 = 27.9$ on one degree of freedom, $p < 0.0001$) detects a significant clinic difference in favor of longer treatment durations in clinic 2. The Wilcoxon test puts relatively more weight on differences between the survival curves at earlier times but also reaches significance ($X^2 = 11.6$ on one degree of freedom, $p = 0.0007$).

Modeling Survival Times

Modeling survival times is useful especially when there are several explanatory variables of interest. For example, the methadone treatment durations of the heroin addicts might be affected by the prognostic variables maximum methadone dose and prison record, as well as the clinic attended. The main approaches used for modeling the effects of covariates on survival can be divided roughly into two classes – *models for the hazard function* and *models for the survival times themselves*. In essence, these models act as analogies of multiple linear regression for survival times containing censored observations, for which regression itself is clearly not suitable.

Proportional Hazards Models

The main technique is due to Cox [6] and known as the *proportional hazards model* or, more simply, *Cox’s regression*. The approach stipulates a model for the hazard function. Central to the procedure is the assumption that the hazard functions for two individuals at any point in time are proportional, the so-called *proportional hazards assumption*. In other words, if an individual has a risk of the event at some initial time point that is twice as high as another individual, then at all later times, the risk of the event remains twice as high. Cox’s model is made up of an unspecified *baseline hazard function*, $h_0(t)$, which is then multiplied by a suitable function of an individual’s explanatory variable values, to give the

individual's hazard function. Formally, for a set of p explanatory variables, $x_1, x_2, \dots, x_p$, the model is

$$h(t) = h_0(t) \exp \left(\sum_{i=1}^p \beta_i x_i \right) \quad (9)$$

where the terms $\beta_1, \dots, \beta_p$ are the parameters of the model that have to be estimated from sample data. Under this model, the *hazard* or *incidence rate ratio*, h_{12} , for two individuals, with covariate values $x_{11}, x_{12}, \dots, x_{1p}$ and $x_{21}, x_{22}, \dots, x_{2p}$ given by

$$h_{12} = \frac{h_1(t)}{h_2(t)} = \exp \left[\sum_{i=1}^p \beta_i (x_{1i} - x_{2i}) \right] \quad (10)$$

does not depend on t . The interpretation of the parameter β_i is that $\exp(\beta_i)$ gives the incidence rate change associated with an increase of one unit in x_i , all other explanatory variables remaining constant. Specifically, in the simple case of comparing hazards between two groups, $\exp(\beta)$, measures the hazard ratio between the two groups. The effect of the covariates is assumed to be multiplicative.

Cox's regression is considered a *semiparametric* procedure because the baseline hazard function, $h_0(t)$, and by implication the probability distribution of the survival times, does not have to be specified. The baseline hazard is left unspecified; a different parameter is essentially included for each unique survival time. These parameters can be thought of as nuisance parameters whose purpose is merely to control the parameters of interest for any changes in the hazard over time. Cox's regression model can also be extended to allow the baseline hazard function to vary with the levels of a stratification variable. Such a *stratified proportional hazards model* is useful in situations where the stratifier is thought to affect the hazard function, but the effect itself is not of primary interest.

A Cox regression can be used to model the methadone treatment times from Table 1. The model uses prison record and methadone dose as explanatory variables, whereas the variable clinic, whose effect was not of interest, merely needed to be taken account of and did not fulfill the proportional hazards assumption, was used as a stratifier. The estimated regression coefficients are shown in Table 2. The coefficient of the prison record indicator variable is 0.389 with a standard error of 0.17. This translates into a hazard ratio of $\exp(0.389) = 1.475$ with a 95% confidence interval ranging from 1.059 to 2.054. In other words, a prison record is estimated to increase the hazard of immediate treatment cessation by 47.5%. Similarly, the hazard of treatment cessation was estimated to be reduced by 3.5% for every extra milligram per day of methadone prescribed.

Statistical software packages typically report three different tests for testing regression coefficients, the *likelihood ratio (LR)* test, the *score test* (which is equivalent to the log-rank test for Cox's proportional hazards model), and the *Wald test*. The test statistic of each of the tests can be compared with a χ^2 distribution to derive a P value. The three tests are asymptotically equivalent but differ in finite samples. The LR test is generally considered the most reliable, and the Wald test, the least. Here, presence of a prison record tests statistically significant after adjusting for clinic and methadone dose (LR test: $X^2 = 5.2$ on one degree of freedom, $p = 0.022$) and so does methadone dose after adjusting for clinic and prison record (LR test: $X^2 = 30.0$ on one degree of freedom, $p < 0.0001$).

Cox's model does not require specification of the probability distribution of the survival times. The hazard function is not restricted to a specific form and, as a result, the semiparametric model has flexibility and is widely used. However, if the assumption of a particular probability distribution for the data is valid, inferences based on such an assumption

Table 2 Parameter estimates from Cox regression of treatment duration on maximum methadone dose prescribed and presence of a prison record stratified by clinic

Predictor variable	Effect estimate			95% CI for $\exp(\beta)$	
	Regression coefficient ($\hat{\beta}$)	Standard error ($\sqrt{\text{var}(\hat{\beta})}$)	Hazard ratio ($\exp(\hat{\beta})$)	Lower limit	Upper limit
Prison record	0.389	0.17	1.475	1.059	2.054
Maximum methadone dose	-0.035	0.006	0.965	0.953	0.978

are more precise. For example, estimates of hazard ratios or median survival times will have smaller standard errors. A *fully parametric proportional hazards model* makes the same assumptions as Cox's regression, but in addition also assumes that the baseline hazard function, $h_0(t)$, can be parameterized according to a specific model for the distribution of the survival times. Survival time distributions that can be used for this purpose, that is, those that have the *proportional hazards property*, are principally the *exponential*, *Weibull*, and *Gompertz* distributions. Different distributions imply different shapes of the hazard function, and, in practice the distribution that best describes the functional form of the observed hazard function is chosen – for details see [1, 2].

Models for Direct Effects on Survival Times

Accelerated failure time models form a family of fully parametric models that assume direct multiplicative effects of covariates on survival times and hence do not rely on proportional hazards. A wider range of survival time distributions possesses the *accelerated failure time property*, principally, the *exponential*, *Weibull*, *log-logistic*, *generalized gamma*, or *lognormal* distributions. In addition, this family of parametric models includes distributions (e.g., the log-logistic distribution) that model unimodal hazard functions, while all distributions suitable for the proportional hazards model imply hazard functions that increase or decrease monotonically. The latter property might be limiting, for example, for modeling the hazard of dying after a complicated operation that peaks in the postoperative period.

The general accelerated failure time model for the effects of p explanatory variables, $x_1, x_2, \dots, x_p$, can be represented as a loglinear model for survival time,

T , namely,

$$\ln(T) = \alpha_0 + \sum_{i=1}^p \alpha_i x_i + \text{error} \quad (11)$$

where $\alpha_1, \dots, \alpha_p$ are the unknown coefficients of the explanatory variables and α_0 an intercept parameter. The parameter α_i reflects the effect that the i th covariate has on log-survival time with positive values indicating that the survival time increases with increasing values of the covariate and *vice versa*. In terms of the original time scale, the model implies that the explanatory variables measured on an individual act multiplicatively, and so affect the speed of progression to the event of interest.

The interpretation of the parameter α_i , then, is that $\exp(\alpha_i)$ gives the factor by which any survival time percentile (e.g., the median survival time) changes per unit increase in x_i , all other explanatory variables remaining constant. Expressed differently, the probability, that an individual with covariate value $x_i + 1$ survives beyond t , is equal to the probability, that an individual with value x_i survives beyond $\exp(-\alpha_i)t$. Hence $\exp(-\alpha_i)$ determines the change in the speed with which individuals proceed along the timescale and the coefficient is known as the *acceleration factor* of the i th covariate.

Software packages typically use the loglinear formulation. The regression coefficients from fitting a log-logistic accelerated failure time model to the methadone treatment durations using prison record and methadone dose as explanatory variables and clinic as a stratifier are shown in Table 3. The negative regression coefficient for prison suggests that the treatment durations tend to be shorter for those with a prison record. The positive regression coefficient for dose suggests that treatment durations tend to be prolonged for those on larger methadone doses. The estimated acceleration factor for an individual with

Table 3 Parameter estimates from log-logistic accelerated failure time model of treatment duration on maximum methadone dose prescribed and presence of a prison record stratified by clinic

Predictor variable	Effect estimate			95% CI for $\exp(\alpha)$	
	Regression coefficient ($\hat{\alpha}$)	Standard error ($\sqrt{\text{var}(\hat{\alpha})}$)	Acceleration factor ($\exp(-\hat{\alpha})$)	Lower limit	Upper limit
Prison record	-0.328	0.140	1.388	1.054	1.827
Maximum methadone dose	0.0315	0.0055	0.969	0.959	0.979

a prison record compared with one without such a record is $\exp(0.328) = 1.388$, that is, a prison record is estimated to accelerate the progression to treatment cessation by a factor of about 1.4. Both explanatory variables, prison record (LR test: $X^2 = 5.4$ on one degree of freedom, $p = 0.021$) and maximum methadone dose prescribed (LR test: $X^2 = 31.9$ on one degree of freedom, $p < 0.0001$) are found to have statistically significant effects on treatment duration according to the log-logistic accelerated failure time model.

Summary

Survival analysis is a powerful tool for analyzing time to event data. The classical techniques Kaplan–Meier estimation, proportional hazards, and accelerated failure time modeling are implemented in most general purpose statistical packages, with the S-PLUS and R packages having particularly extensive facilities for fitting and checking nonstandard Cox models, see [7]. The area is complex and one of active current research. For additional topics such as other forms of censoring and *truncation* (delayed entry), *recurrent events*, models for *competing risks*, *multistate models* for different transition rates, and *frailty models* to include random effects the reader is referred to [7–10].

Syndromic Surveillance

Syndromic surveillance (see **Managing Infrastructure Reliability, Safety, and Security; Game Theoretic Methods; Digital Governance, Hotspot Detection, and Homeland Security; Sampling and Inspection for Monitoring Threats to Homeland Security**) has been defined as “the ongoing, systematic collection, analysis, interpretation, and application of real-time (or near-real-time) indicators of diseases and outbreaks that allow for their detection before public health authorities would otherwise note them” [1]. It has also been defined as “...surveillance using health-related data that precedes diagnosis and signals a sufficient probability of a case or an outbreak to warrant further public health response” [2]. These definitions focus on a number of concepts important to syndromic surveillance:

1. Syndromic surveillance is public health surveillance, not military, regulatory, or intelligence surveillance.
2. The surveillance is based on the ongoing, routine collection of “health-related” data, such as counts of individuals coming into medical facilities, over-the-counter medication sales, and aggregate laboratory test results, that is generally collected for some purpose other than surveillance.
3. The data and associated surveillance are intended to provide leading indicators that “precede diagnosis” or “case” confirmation with the goal of providing early warning of an outbreak.
4. The system must provide timely signals that trigger “further public health response” while simultaneously minimizing the number of false alarms [2].

A *syndrome* is “A set of symptoms or conditions that occur together and suggest the presence of a certain disease or an increased chance of developing the disease” [3]. In the context of syndromic surveillance, a syndrome is a set of nonspecific pre-diagnosis medical and other information that may indicate the release of a bioterrorism agent or natural disease outbreak (see, for example, Syndrome Definitions for Diseases Associated with Critical

Bioterrorism-associated Agents [4]). The data in syndromic surveillance systems may be clinically well-defined and linked to specific types of outbreaks, such as groupings of ICD-9 codes from emergency room “chief complaint” data, or only vaguely defined and perhaps only weakly linked to specific types of outbreaks, such as over-the-counter sales of cough and cold medication or absenteeism rates.

Since its inception, syndromic surveillance has focused mainly on *early event detection*: (see **Fault Detection and Diagnosis; Behavioral Decision Studies; Public Health Surveillance**) gathering and analyzing data in advance of diagnostic case confirmation to give early warning of a possible outbreak. Such early event detection is not supposed to provide a definitive determination that an outbreak is occurring. Rather, it is supposed to signal that an outbreak *may* be occurring, indicating a need for further evidence or triggering an investigation by public health officials (i.e., the Centers for Disease Control and Prevention (CDC) or a local or state public health department).

More recently, the purpose of syndromic surveillance has been expanded to include using “existing health data in real time to provide immediate analysis and feedback to those charged with investigation and follow-up of potential outbreaks” [5]. This broader focus on *electronic biosurveillance* includes both early event detection and *situational awareness* [2]. Situational awareness is the real-time analysis and display of health data to monitor the location, magnitude, and spread of an outbreak, as well as the availability and application of public health and medical resources in response to the outbreak. As Bravata *et al.* [6] said, “...an essential component of preparations for illnesses and syndromes potentially related to bioterrorism includes the deployment of surveillance systems that can rapidly detect *and monitor* [emphasis added] the course of an outbreak and thus minimize associated morbidity and mortality”.

Syndromic surveillance is one form of *public health surveillance* (see **Lead; Cohort Studies; Digital Governance, Hotspot Detection, and Homeland Security**), which is the “ongoing, systematic collection, analysis, interpretation, and dissemination of data regarding a health-related event for use in public health action to reduce morbidity and mortality and to improve health” [7]. In terms of bioterrorism, syndromic surveillance uses medical and health-related data, which is distinct from other types of detection

methods such as air or water sampling for pathogens (e.g., the BioWatch program [8, 9]). Some syndromic surveillance systems may be useful for epidemic monitoring, though such monitoring can be and is currently conducted *via* a variety of methods.

Syndromic surveillance is an emerging tool in epidemiology – the study of the distribution, determinants, and occurrence of disease and health-related conditions in populations [10, p. 1]. However, there are a number of characteristics that distinguish syndromic surveillance from public health surveillance and epidemiology as they have traditionally been practiced. For example, syndromic surveillance uses nonspecific health-related data. Traditional notifiable disease reporting is based on suspected or confirmed cases. Syndromic surveillance systems are intended to actively search for evidence of possible outbreaks, where the type of outbreak is not specified in advance. In conventional public health surveillance, it is unusual to initiate active surveillance without a suspected outbreak.

Traditional epidemiological methods tend to focus on retrospective studies initiated to address a specific population risk event. In comparison, syndromic surveillance systems designed for early event detection do not have a specific risk event focus. This lack of a specific focus leads to difficult questions about how to aggregate data – syndromically, spatially, and temporally – and to questions of what types of models and detection methods are most appropriate. Given that the data is usually in-hand, in classic retrospective epidemiological studies these types of questions can be directly resolved. Yet, conducting a retrospective study to try to understand the cause of a disease or outbreak can still be quite challenging. Implementing and operating a system intended to effectively detect a wide variety of possible outbreaks that have not yet occurred, from naturally occurring diseases to bioterrorism attacks, is a daunting task.

Surveillance Systems

The CDC and many state and local health departments around the United States are actively developing and fielding electronic biosurveillance systems, such as the CDC's BioSense system. Sosin [11] states that approximately 100 state and local health jurisdictions were conducting some form of syndromic

surveillance in 2003. In 2004, Bravata *et al.* [6] conducted a systematic review of the publicly available literature and various websites from which they identified 115 surveillance systems, of which they found 29 that were designed specifically for detecting bioterrorism.

Examples of Systems Currently in Use

Below are brief descriptions of three surveillance systems chosen to illustrate large-scale systems currently in operation. The first two are true systems, in the sense that they are comprised of both dedicated computer hardware and software. The third is more properly described as a set of software programs that can be freely downloaded and implemented by any public health organization.

- **BioSense** (www.cdc.gov/biosense)
Developed and operated by the CDC, BioSense is intended to be a United States-wide electronic biosurveillance system. Begun in 2003, BioSense initially used Department of Defense and Department of Veterans Affairs outpatient data along with medical laboratory test results from a nationwide commercial laboratory. In 2006, BioSense began incorporating data from civilian hospitals as well. The primary objective of BioSense is to “expedite event recognition and response coordination among federal, state, and local public health and healthcare organizations” (J. Tokars, Personal communication, 2006) [12, 13].
- **ESSENCE** (www.geis.fhp.osd.mil/GEIS/SurveillanceActivities/ESSENCE/ESSENCE.asp)
ESSENCE is an acronym for *Electronic Surveillance System for the Early Notification of Community-based Epidemics*. Developed by the Department of Defense in 1999, ESSENCE IV now monitors for infectious disease outbreaks at more than 300 military treatment facilities worldwide on a daily basis using data from patient visits to the facilities and from pharmacy data. For the Washington DC area, ESSENCE II monitors military and civilian outpatient visit data as well as over-the-counter pharmacy sales and school absenteeism [14–16]. Though ESSENCE has gone through a number of iterations, the subsequent versions have been strongly influenced by the original military project (H. Burkom, Personal communication, 2006).

- **EARS** (www.bt.cdc.gov/surveillance/ears/) EARS is an acronym for *Early Aberration Reporting System*.

Developed by the CDC, EARS was designed for monitoring for bioterrorism during large-scale events that often have little or no baseline data (i.e., as a short-term *drop-in* surveillance method) [17]. For example, the EARS system was used in the aftermath of Hurricane Katrina to monitor communicable diseases in Louisiana [18], for syndromic surveillance at the 2001 Super Bowl and World Series, as well as at the Democratic National Convention in 2000 [19]. Though developed as a drop-in surveillance method, EARS is now being used on an ongoing basis in many syndromic surveillance systems.

Descriptions of some state and local syndromic surveillance systems (as well as other information) can be found in [20, 21].

Components of Electronic Biosurveillance Systems

Electronic biosurveillance systems comprise a series of functional components. Expanding on Rolka [22], an ideal system will contain all of the components listed below.

- The original data, of which access is gained only after appropriately addressing legal and regulatory requirements, as well as personal privacy and proprietary issues.
- Computer hardware and information technology for (near) real-time assembly, recording, transfer, and preprocessing of data.
- Data management subject matter experts, software, and techniques for processing incoming data into analytic databases, as well as processes and procedures for managing and maintaining these databases.
- Statistical algorithms to analyze the data for possible outbreaks over space and time that are of sufficient sensitivity to provide signals within an actionable timeframe while simultaneously limiting false positive signals to a tolerable level.
- Public health experts with sufficient statistical expertise that can appropriately choose and apply the algorithms most relevant to their jurisdiction and appropriately interpret the signals when they occur.

- Data display and query software, as well as the necessary underlying data, that facilitates rapid and easy investigation and adjudication of signals by public health experts, including the ability to “trace back” from signal to likely source.
- Other data displays, combined with decision support and communication tools, to support situational awareness during an outbreak to facilitate effective and efficient public health response.

Mandl *et al.* [23], in *Implementing Syndromic Surveillance: A Practical Guide Informed by the Early Experience*, provides a detailed discussion of what is required and guidance about how to implement syndromic surveillance systems.

Quantitative Methods Used in Biosurveillance Systems for Early Event Detection

Biosurveillance systems use a variety of temporal and spatial methods for early event detection. As is discussed in more detail below, most of these have been adapted from other fields and applications. Buckeridge *et al.* [24] provides a useful classification of common surveillance scenarios and a mapping of some early event detection methods to those scenarios.

Situational awareness is an emerging concept in electronic biosurveillance and, as such, specific methods for assessing and displaying relevant information has not yet been incorporated into the systems. Currently, situational awareness is limited to displaying the spatial distribution of data *via* geographic information system (GIS) software (see, for example, Li *et al.* [25]).

Temporal Methods

Most syndromic surveillance systems apply variants of the standard univariate statistical process control (SPC) methods (*see Credit Scoring via Altman Z-Score; Reliability Integrated Engineering Using Physics of Failure; Sampling and Inspection for Monitoring Threats to Homeland Security*): Shewhart, cumulative sum (CUSUM), and/or exponentially weighted moving average (EWMA) charts. Woodall [26] provides a comprehensive overview of the application of control charts to health surveillance. Montgomery [27] is an excellent introduction

to these methods in a SPC setting. Shmueli and Fienberg [28] and Shmueli [29] give a review of these and other methods potentially applicable to early event detection in a biosurveillance setting.

The challenge in applying these methods is that syndromic surveillance generally violates classical SPC assumptions, particularly the assumptions of normality and independent and identically distributed observations. Biosurveillance data is generally autocorrelated and frequently has seasonal periodicities. Further, given the goal of quick detection, methods are usually run on individual observations for which an assumption of normality generally does not apply.

In spite of this, the standard SPC methods are sometimes applied with little modification (see, for example, Fricker [30] or Stoto *et al.* [31]) and in some cases the methods are modified to attempt to account for the autocorrelation. For example, EARS [17] applies variants of the Shewhart chart (see equations (1) and (2)) and a cumulative method motivated by the CUSUM (see equation (3)). These methods use various moving windows of data to estimate the process mean and standard deviation [19] and they are intended to be used when little historic (“baseline”) information is available.

The EARS methods are called C_1 , C_2 , and C_3 and are defined as follows [32] (L. Hutwagner, Personal communication, 2006). Let $X(t)$ be an observation for period t , for example the number of individuals presenting to a particular hospital with a specific syndrome on day t . The C_1 method calculates the statistic $C_1(t)$ for day t as

$$C_1(t) = \frac{X(t) - \bar{X}_1(t)}{s_1(t)} \quad (1)$$

where $\bar{X}_1(t) = \sum_{i=t-1}^{t-7} X(i)/7$ and $s_1(t) = \sqrt{\sum_{i=t-1}^{t-7} (X(i) - \bar{X}_1(t))^2/6}$. It signals an alarm at time t when the C_1 statistic exceeds a *threshold* which is fixed at three standard deviations above the moving sample average: $C_1(t) > 3$.

The C_2 method is similar to the C_1 method, but incorporates a 2-day lag in the mean and standard deviation calculations. It calculates

$$C_2(t) = \frac{X(t) - \bar{X}_3(t)}{s_3(t)} \quad (2)$$

where $\bar{X}_3(t) = \sum_{i=t-3}^{t-9} X(i)/7$ and $s_3(t) = \sqrt{\sum_{i=t-3}^{t-9} (X(i) - \bar{X}_3(t))^2/6}$, and signals an alarm when $C_2(t) > 3$.

Finally, the C_3 method uses the C_2 statistics from the past 3 days, calculating the statistic $C_3(t)$ for day t as

$$C_3(t) = \sum_{i=t-3}^{t-2} \max[0, C_2(i) - 1] \quad (3)$$

It signals an alarm when $C_3(t) > 2$.

BioSense originally implemented the C_1 , C_2 , and C_3 methods, but has since modified the C_2 . Calling the new method “W2”, it calculates the mean and standard deviation separately for weekdays and weekends (using the relevant last 7 days with a 2-day lag). Following the suggestion of Buckeridge *et al.* [24], it uses an empiric method to define the threshold and users of the system can select the threshold as an option [33].

To date, multivariate SPC methods have not been incorporated into operational electronic biosurveillance systems. Some research has been conducted to define and evaluate directional multivariate methods, including Fricker *et al.* [34], Fricker [30], Stoto *et al.* [31], and Joner *et al.* [35]. Whether or not multivariate methods provide additional sensitivity to detect outbreaks compared to the current practice of using multiple simultaneous univariate methods is yet to be conclusively demonstrated. Various methods have also been proposed to combine and/or adjust for the application of multiple univariate methods in multivariate settings. See the discussion in Rolka *et al.* [36] about parallel and consensus monitoring methods and Stoto *et al.* [31, 37] for a discussion and an evaluation of some of these methods.

Regression and time series methods have also been proposed to explicitly model, and hence account for, seasonality. The basic idea is to model the disease incidence process, perhaps including terms in the model for annual seasonal variations, monthly variations, and even day of the week and holiday variations. The model is then used to either: (a) predict the expected number of events and the difference between the expected number and observed number is monitored for excessive deviations or, (b) model and then remove the explainable/known effects (sometimes called *preconditioning*) and then the residuals are monitored using traditional SPC

methods. This is consistent with recommendations by Montgomery [27] for autocorrelated data.

Examples in the literature include Fricker *et al.* [38], Brillman *et al.* [39], who apply the CUSUM to the prediction errors, the CDC's cyclical regression models discussed in Hutwagner *et al.* [19], log-linear regression models in Farrington *et al.* [40], and time series models in Reis and Mandl [41]. See Shmueli [29] for additional discussion of the use of regression and time series methods for syndromic surveillance and Burkom *et al.* [42] for a comparison of two regression-based methods and an exponential smoothing method applied to biosurveillance forecasting. Also see Lotze *et al.* [43] for a detailed discussion of preconditioning applied to syndromic surveillance data.

Other temporal methods that have been proposed or are in use for syndromic surveillance include: wavelets (see Goldberg *et al.* [44], Zhang *et al.* [45], Shmueli [46], and the discussion in Shmueli [29]); Bayesian networks (see Wong *et al.* [47], Rolka *et al.* [36]); hidden Markov models (see Le Strat and Carrat [48]); Bayesian dynamic models (see, for example, Sebastiani *et al.* [49]), and rule-based methods (see, for example, Wong *et al.* [50]).

Spatial and Spatiotemporal Methods

Kleinman *et al.* [51] and Lazarus *et al.* [52] proposed a generalized linear mixed model (GLMM) (see **Bayesian Statistics in Quantitative Risk Assessment**) to simultaneously monitor disease counts over time in a region divided into smaller subareas (zip codes). It is statistically attractive because it uses information across the entire region while appropriately adjusting for the smaller areas (see **Statistics for Environmental Toxicity; Environmental Remediation**).

As described in Kleinman *et al.* [51], there are two forms of the model depending on whether individual data and covariates are available versus aggregated counts and covariates by zip code. In the former case, the model is

$$E(y_{ijt}|b_i) = p_{ijt} \quad \text{and} \quad \text{logit}(p_{ijt}) = \mathbf{x}_{ijt}\boldsymbol{\beta} + b_i \quad (4)$$

where y_{ijt} is an indicator for whether or not person j in area i is a case on day t , p_{ijt} is the probability he or she is a case, $\mathbf{x}_{ijt}$ is a vector of observed covariates on person j and/or area i over time up to and including

day t , $\boldsymbol{\beta}$ is a vector of fixed effects, and b_i is a random effect for area i . When no individual level covariate information is available, the most likely situation, the model is

$$E(y_{it}|b_i) = n_{it} p_{it} \quad \text{and} \quad \text{logit}(p_{it}) = \mathbf{x}_{it}\boldsymbol{\beta} + b_i \quad (5)$$

where $y_{it} = \sum_{j=1}^{n_{it}} y_{ijt}$. In this model, p_{it} can be thought of as the probability that each individual in area i will be a case on day t .

Having fit the model in equation (5), z cases are observed on day $t + 1$. The rarity of the observed count is assessed by calculating

$$\Pr(Z \geq z \text{ cases}) = 1 - \sum_{k=1}^{z-1} \binom{n_{it}}{k} \hat{p}_{it}^k (1 - \hat{p}_{it})^{n_{it}-k} \quad (6)$$

where $\hat{p}_{it}$ is calculated from the estimated coefficients in the usual way for logistic regression and $1/(\hat{p}_{it} \times \text{number of tests conducted})$ is proposed as the *recurrence interval*: the number of time periods for which the expected number of counts of z or more cases is one (Woodall *et al.* [53]). Waller [54] recommends an alternate calculation for the recurrence interval and Woodall *et al.* [53] take issue with both the use of and recommended calculations for the recurrence interval.

The small area regression and testing ("SMART") method in BioSense (see the BioSense User Guide [55]) is based on the Kleinman *et al.* [51] and Lazarus *et al.* [52] GLMM approach. However, as implemented in BioSense it only uses spatial information to bin data into separate time series, the output of which are subsequently combined using a Bonferroni correction. Hence, the BioSense SMART method is properly classified as a temporal method (H. Burkom, Personal communication, 2006).

The most commonly used spatial method is the scan statistic, particularly as implemented in the SaTScan software (www.satscan.org). Originally developed to retrospectively identify disease clusters (see Kulldorff [56]), the method is now regularly used prospectively in electronic biosurveillance systems (see Kulldorff [57]). For example, it was used as part of a drop-in syndromic surveillance system in New York City after the 9/11 attack (Ackelsberg *et al.* [58]). While it has been studied by the BioSense program, it has not yet been implemented in the BioSense system interface (see Bradley [59] and the BioSense User Guide [55]).

The basic idea in SaTScan is to count the number of cases that occur in a cylinder, where the circle is the geographic base and the height of the cylinder corresponds to time. The cylinder is passed over space, varying the radius of the circle (up to a maximum radius that includes 50% of the monitored population) and the height of the cylinder and counts of cases for those geographic regions whose centroids fall within the circle for the period of time specified by the height of the cylinder are summed. When used for prospective biosurveillance, the start date of the height of the cylinder is varied but the end date is fixed at the most current time period. Conditioning on the expected spatial distribution of observations, SaTScan reports the most likely cluster (in both space and time) and its p value.

Though widely used, some aspects of the prospective application of the SaTScan methodology have been questioned, particularly the use of recurrence intervals and performance comparisons between SaTScan and other methods. See Woodall *et al.* [53] for further details. Also, see Kulldorff [57] for other methods for disease mapping and for testing whether an observed pattern of disease is due to chance.

Olson *et al.* [60] and Forsberg *et al.* [61] take an alternate approach to assessing possible disease clusters using M-statistics based on the distribution of pairwise distances between cases. That is, let $\mathbf{X} = \{X_1, \dots, X_n\}$ represent the locations of n cases on the plane and let $\mathbf{d} = \{d_1, \dots, d_{\binom{n}{2}}\}$ be the $\binom{n}{2}$ interpoint distances, then the M-statistic is

$$M = (\mathbf{o} - \mathbf{e})^T \hat{S}^{-1} (\mathbf{o} - \mathbf{e}) \quad (7)$$

where $\mathbf{o}$ and $\mathbf{e}$ are vectors of observed and expected counts of binned interpoint distances and $\hat{S}^{-1}$ is the inverse of the estimate of the covariance matrix.

Other approaches to spatial and spatiotemporal biosurveillance methods include the repeated two-sample rank procedure of Fricker and Chang [62], the automated epidemiologic geotemporal integrated surveillance system (AEGIS) by Olson *et al.* [63] and the application of CUSUM methods to the spatial distribution of cases (see Rogerson and Yamada [64]). See Lawson and Kleinman [65] for additional exposition and methods, and Mandl *et al.* [23] for further discussion on spatial and spatiotemporal modeling issues. For spatial methods with application to more traditional public health data and problems, see Waller and Gotway [66].

Issues and Challenges in Biosurveillance

A number of papers discuss the various issues, challenges, and important research needs associated with effective implementation and operation of electronic biosurveillance systems. These include Sosin [1], Fricker and Rolka [2], Bravata *et al.* [6], Rolka [22], Shmueli [29], Stoto *et al.* [32], and Buehler *et al.* [67]. Research challenges span many disciplines and problems, from legal and regulatory challenges that must be resolved to gain access to data, to the technological challenges of designing the computer hardware and software for collecting and assembling the data, to the ethical and procedural issues for managing and safeguarding the data, to the quantitative challenges of analyzing the data for potential outbreaks and displaying the data to enhance situational awareness, to the managerial challenges of effectively assembling and operating the entire system.

Much of the controversy surrounding syndromic surveillance stems from the initial focus on early event detection, a use that requires a number of (as yet unproven) assumptions, including:

- Leading indicators of outbreaks exist in prediagnosis health-related data of sufficient strength that they are statistically detectable.
- The leading indicators occur sufficiently far in advance of clinical diagnoses so that, when found, they provide the public health community with sufficient advance notice to take action.

Reingold [68] has suggested that a compelling case for the implementation of syndromic surveillance systems is yet to be made and Stoto *et al.* [37] have questioned whether syndromic surveillance systems can achieve an effective early detection capability.

However, a myopic focus only on early event detection for bioterrorism in syndromic surveillance systems misses other important benefits electronic biosurveillance can provide, particularly the potential to significantly advance and modernize the practice of public health surveillance. For example, whether or not electronic biosurveillance systems prove effective at the early detection of bioterrorism, they are likely to have a significant and continuing role in the detection of seasonal and pandemic flu, as well as other naturally occurring disease outbreaks. This

latter function is echoed in an Institute of Medicine report on *Microbial Threats to Health* [69]:

“[S]yndromic surveillance is likely to be increasingly helpful in the detection and monitoring of epidemics, as well as the evaluation of healthcare utilization for infectious diseases.”

In terms of bioterrorism, Stoto [70] states that electronic biosurveillance systems build links between public health and healthcare providers – links that could prove to be critical for consequence management should a bioterrorism attack occur. Furthermore, Sosin [1] points out that electronic biosurveillance systems can:

- act as a safety net, should the existing avenues of detection fail to detect an outbreak, so countermeasures can be taken swiftly;
- provide additional lead time to public health authorities so that they can take more effective public health actions.

The safety net idea says that detection in a biosurveillance system does not necessarily have to be earlier than the first clinical diagnosis to be useful. To illustrate, a Dutch biologist conducting automated salmonella surveillance related that a surveillance system detected outbreaks whose occurrence was somehow missed by sentinel physicians (H. Burkom, Personal communication, 2006). And the idea of additional lead time is that unusual indicators in an electronic biosurveillance system (not necessarily a signal from an early event algorithm) may give public health organizations time to begin organizing and marshaling resources in advance of a confirmed case and/or provide critical information about how and where to apply the resources.

Conclusion

Electronic biosurveillance systems are being developed and implemented around the world. They are motivated by a need for improved public health surveillance, not only for bioterrorism, but also to improve detection and responsiveness to natural disease outbreaks such as avian influenza and severe acute respiratory syndrome (SARS), and as such they hold great promise as public health tools.

For those interested in additional information, the International Society for Disease Surveillance (<http://syndromic.org>) is a professional society devoted to advancing the field of disease surveillance, and *Advance in Disease Surveillance* (www.isdsjournal.org/) is its journal.

Acknowledgments

I would like to thank Howard Burkom, Lori Hutwagner, Michael Jackson, Galit Shmueli, Mike Stoto, Jerry Tokars, Lance Waller, and Bill Woodall for their helpful and thoughtful comments on an early version of this article. It has been significantly improved as a result of their input. Any errors or omissions that may remain are solely my responsibility.

RONALD D. FRICKER

Systems Reliability

Systems reliability assessment (see **Reliability Growth Testing; Reliability Data; Mathematics of Risk and Reliability: A Select History**) is the term commonly applied to the prediction of system performance parameters such as the likelihood or frequency of system failure in a specified mode. Depending on the task the system performs, the relevant system failure parameter could be the probability of failure at a point in time (unavailability), the chance that the system has not functioned without failure over a period of time (unreliability), or the rate at which the system fails (failure rate). System quantification can also produce importance measures, that indicate the contribution that each component makes to the system failure mode. These measures provide a numerical indicator between 0 and 1 and account for the component failure likelihood and the system structure. If the component can, on its own, cause the system failure, it is usually ranked higher than if it were, for example, part of a redundant structure and would need to fail in conjunction with other components to cause system malfunction.

Systems are designed to perform a specific function and when they fail they can fail in different ways known as modes. For example, a safety system designed to shut a process down when a hazard occurs can fail in a way where it is incapable of detecting and responding to the hazard or it can fail spuriously and produce a shutdown when the hazard does not exist. The system assessment needs to focus on one particular failure mode rather than a generic failure. The system is made up of components that can also fail in different ways. The state of the system is a function of the state of the components. The system failure modes are caused by component failures either occurring individually or in combinations.

Many systems are safety critical and have the potential to fail in a way that results in fatalities. For this type of system, its reliability or failure frequency is commonly assessed as part of a risk assessment undertaken to ensure that an acceptable level of performance can be expected. The system analysis is best carried out as part of the system design process, when there is the greatest flexibility to effect change. When used as part of a risk assessment, the probability or frequency of a hazardous event

is judged in conjunction with the consequences of the event. Risk [1] is defined as $\text{risk} = \text{frequency} \times \text{consequences}$.

There may be several potential hazards for a system, and its total risk is the sum of the risks posed by each hazard. This measure is then used to judge the acceptability of the system performance.

For new system designs, while the system in its entirety does not exist, the components used in its construction, or similar ones, are likely to be part of other systems. The failure characteristics of the components can be studied and, using the historical data, failure time distributions can be constructed. Taking account of the maintenance process to give times to repair, the failure likelihood of each component can be predicted. Systems reliability uses the historical performance of the components and the proposed structure or architecture of the system (defining how the components are linked).

There are a variety of methods that can be used to predict the system failure probability or frequency. They make different assumptions about the way the system is operated and maintained. The selection of one method rather than another to perform the analysis is dependent upon how closely the assumptions of the method match the operating condition for the system. There can be two outcomes from the analysis, qualitative and quantitative. The qualitative analysis yields the combinations of component events that cause the system failure mode of concern. These are termed minimal cut sets and are formally defined and discussed later in this article. Quantification produces the system failure likelihood and frequency measures.

This article describes the alternative modeling techniques for systems reliability assessment. An overview of the methods is provided, along with the assumptions implicit in each method. Guidelines on when it is appropriate to select a particular method for a system assessment are then given. A detailed presentation of the methods presented here can be found in [2, 3].

Combinatorial Methods

Combinatorial methods are a category of techniques which determine the combinations of component failures which can cause the system failure as an intermediate step in producing system performance predictions. Appropriate models are used to calculate

the likelihood of each component failure mode. Then, assuming all components fail independently (the failure of one component does not affect the likelihood of failure of any other) the component failure parameters (see **Simulation in Risk Management; Reliability Data; Markov Modeling in Reliability**) are used in conjunction with the list of the failure combinations to evaluate the likelihood of system failure. Within this class of techniques are reliability networks and the fault tree method. The assumption of component failure independence is central to these techniques, which differ in the way they represent the system architecture.

The models used to calculate the component failure probabilities are common to both methods. Usually, as in the models given in equations (1) and (2), they introduce another assumption of a constant failure rate, though this is not a limitation of the combinatorial methods and alternative models can be used.

Revealed Component Failures

When the system operation is such that a component failure is revealed, then its repair can be immediately instigated. For components that have a constant failure rate, λ , and repair rate, ν , the probability, $q(t)$, that it has failed at time t is given by

$$q(t) = \frac{\lambda}{\lambda + \nu} (1 - e^{-(\lambda + \nu)t}) \quad (1)$$

For nonrepairable components, $\nu = 0$.

Dormant Component Failures

When the component is not actively involved in the system operation at the point that it fails, for example, part of a standby system, it may not be noticed that the failure has occurred. The fact that this type of component has failed is usually discovered when a demand is placed on it to function or when a test identifies the failure. For such components tested at regular time intervals of θ with mean time to repair τ , the average component unavailability q_{AV} is approximated by

$$q_{AV} = \lambda \left(\frac{\theta}{2} + \tau \right) \quad (2)$$

Reliability Networks (Reliability Block Diagrams)

The Reliability Network approach, sometime known as the *reliability block diagram* (see **Multistate Systems; Probabilistic Risk Assessment**) or RBD [4] method was the first technique used to assess system reliability. The network consists of nodes, which represent the component failure modes, and edges, which link the component failure events according to the structure of the system.

A typical reliability network is shown in Figure 1. A “start node” is placed in the far left of the network and an “end node”, at the far right. Nodes are then incorporated in the network according to how the component failure mode that they represent influences the system functionality. If a component functions then there is a path through the component node. Paths through the network go in a direction from left to right. If vertical edges appear in the network, flow through them can be in either direction. The occurrence of the component failure mode means that there can be no path through the associated node. If there is a path through the network that connects the start node to the end node, then the system is considered to function. System failure occurs when the component failures in the system cause a cut through the network that isolates the start node from the end node. For fully redundant systems where it requires all components to fail in order to cause failure of the system, the reliability network is a parallel structure. Nonredundant systems that cannot tolerate the failure of any component result in a series system. For the network shown in Figure 1, components A and B are in parallel, and this section is in series with component C. Should components A and B both fail or component C fail on its own, there would be no path through the network, and under either of these conditions, the system can be considered to have failed.

For quantification of the system failure probability (see **Repair, Inspection, and Replacement Models**;

Figure 1 Simple reliability network

Imprecise Reliability; Markov Modeling in Reliability), the network can be categorized as either “simple” or “complex”. Simple networks are those whose structure is made from independent series and parallel sections. “Complex” networks are those that do not fall into this category.

The unreliability of simple systems can be obtained by taking each series or parallel section (of, say, n components) and replacing it by a “virtual” component having the same reliability characteristics as the section. So, for series sections, which are nonredundant, the section unreliability Q_{ser} can be calculated from

$$Q_{\text{ser}} = 1 - \prod_{i=1}^n (1 - Q_i) \quad (3)$$

Parallel, fully redundant sections, have unreliability Q_{par} given by

$$Q_{\text{par}} = \prod_{i=1}^n Q_i \quad (4)$$

where Q_i is the failure probability of each of the n components in the section.

The process continues until there is a single virtual component between the start and end nodes of the network. The reliability of this virtual component is the reliability of the system. For example, in the network shown in Figure 1, the reduction is performed in two stages. The first calculates the unreliability of the parallel structure containing components A and B. In the second step, this new virtual component is treated as being in series with component C. This yields the system unreliability for the network. While this method works for simple network configurations, a generalized method is required that should work whatever the structure of the network. This is based on finding the causes of system failure.

The network can be analyzed to produce the system failure modes known as *minimal cut sets*. The concept of a *cut set* is defined as a set of component failure modes which, if they occur together, would cause the system to fail in the mode of concern. The cut set is, however, of little use as it may exceed the required conditions for the system to fail. For example, {A,C} is a cut set of the network in Figure 1. As soon as component C has failed, however, the system has already failed, and the failure of component A is not a necessary condition

for system failure. The more useful concept is that of the *minimal cut set*; this is a minimal (necessary and sufficient) combination of component failures, which, if they occur, would result in system failure. For the network of Figure 1, there are two minimal cut sets {A,B} and {C}. The name cut set is used because these combinations cause a cut through the network.

The reliability network also has the capability of being viewed from the complementary viewpoint of system failure, the system success. It is possible to determine the working component conditions required for system functionality. This gives rise to the concept of a *path set* which is a combination of working component states that guarantee that the system works. A *minimal path set* is a minimal set of functioning components that will cause the system to function. For the system shown in Figure 1 the minimal path sets are {A,C} and {B,C}.

Consider the well-known “bridge” network structure, which is shown in Figure 2. This network cannot be sequentially reduced in series and parallel sections to determine the system reliability.

Any network in this category is classed as “complex”, and the approach is to first determine the list of minimal cut sets, $C_i, i = 1, \dots, N_c$, where N_c is the total number of minimal cut sets and + represents the logical OR operator. The causes of system failure, SYS, can then be expressed as

$$SYS = C_1 + C_2 + \dots + C_{N_c} \quad (5)$$

The likelihood for system failure is then given in by the inclusion–exclusion expansion:

$$\begin{aligned} Q_{\text{sys}} = & \sum_{i=1}^{N_c} P(C_i) - \sum_{i=2}^{N_c} \sum_{j=1}^{i-1} P(C_i \cap C_j) \\ & + \sum_{i=3}^{N_c} \sum_{j=2}^{i-1} \sum_{k=1}^{j-1} P(C_i \cap C_j \cap C_k) - \dots \\ & + (-1)^{N_c+1} P(C_1 \cap C_2 \dots \cap C_{N_c}) \end{aligned} \quad (6)$$

Figure 2 The classical “bridge” network

For the bridge system shown in Figure 2, there are four minimal cut sets: {A,B}, {A,C,E}, {B,C,D}, and {D,E}. If the failure probability of component i is q_i , then the system failure probability is (after simplification)

$$\begin{aligned} Q_{\text{SYS}} = & q_A q_B + q_D q_E + q_A q_C q_E + q_B q_C q_D \\ & - q_A q_B q_D q_E - q_A q_B q_C q_E - q_A q_B q_C q_D \\ & - q_A q_C q_D q_E - q_B q_C q_D q_E - 2 q_A q_B q_C q_D q_E \quad (7) \end{aligned}$$

This small example still has 15 terms in the full expansion of equation (7). For all, but the smallest of systems, this expansion becomes prohibitively expensive in terms of computer processing time even for fast digital computers, and approximations are required.

The approximation needs to be an upper bound to take a pessimistic view of the system performance, especially when the system being analyzed is a safety system. A common approximation is the minimal cut set upper bound, Q_{MCSU} , given in equation (8). This provides a good estimation of the system failure probability and, when the minimal cut sets are independent (do not have any component failure events in common) the equation is exact.

$$Q_{\text{MCSU}} \leq 1 - \prod_{i=1}^{N_c} (1 - P(C_i)) \quad (8)$$

For the bridge network problem, the minimal cut set upper bound is:

$$\begin{aligned} Q_{\text{SYS}} \approx & 1 - (1 - q_A q_B)(1 - q_D q_E) \\ & (1 - q_A q_C q_E)(1 - q_B q_C q_D) \quad (9) \end{aligned}$$

Fault Tree Analysis

Fault tree analysis (*see Canonical Modeling; Fault Detection and Diagnosis; Expert Judgment*) is the most commonly used technique to assess the failure probability of a specific system failure mode in terms of the failure likelihood of its components. The concept was developed by Watson [5] at Bell Telephone Laboratories in 1961. The time-dependent mathematical theory, known as *kinetic tree theory*, was developed by Vesely at Idaho Nuclear Laboratories and appeared almost 10 years after the initial conception [6]. Kinetic tree theory remains the method used

today in many of the commercially available software tools that perform fault tree analysis.

The fault tree diagram is an inverted tree structure that starts with the system failure mode event, known as *the top event*. Its branches then spread downwards, systematically developing the failure logic, firstly, in terms of intermediate system events down to component failure events, known as *basic events*, which terminate the branches as illustrated in Figure 3 (developing the failure logic in sections from left to right for convenience of presentation).

The fault tree diagram features two types of symbols: events and gates. The event symbols enable the failure logic to be documented as shown. The logic expressing how the events combine to cause the events appearing at higher levels in the tree is indicated by gate symbols. Two of the fundamental gate types are the AND gate and the OR gate. The AND gate symbol (as shown for the GATE 1 event in Figure 3) represents a fully redundant structure. It has events from the lower level in the fault tree as inputs, and the higher level event (the gate output) occurs if all inputs to the gate occur. The OR gate (symbol for TOP) is used to represent a nonredundant structure, and the output to the gate occurs when at least one of the input events occurs. There are many other symbols that can be used [3], but they are mainly for the purposes of the documentation.

There are three fundamental mathematical logic operators (AND, OR, and NOT). For certain system types, the use of the NOT gate is required in the analysis [7], which means that NOT component failure events, i.e., components successfully working, contribute to the failure of the system. This is known as *noncoherence*.

Having constructed the fault tree, it can be analyzed qualitatively and quantitatively. The qualitative analysis produces minimal cut sets by performing Boolean reduction on the failure logic structure. Quantitative analysis delivers the system failure mode probability and frequency. It is also possible to extract importance measures.

As an example, consider the simple tank level control system shown in Figure 4 [8]. Initially, the system has the push button contacts open and switches 1 and 2 (SW1, SW2) contacts closed. To start the system, the push button is pressed and held. This energizes relay R1, which closes its contacts and maintains the circuit when the push button is released

Figure 3 Fault tree for top event “tank overfills”

and opens. Relay R2 is also energized and its contacts close, starting the pump in the second circuit. The pump transfers fluid to the tank. The level of the fluid in the tank is monitored by two level sensors L1 and L2. When the fluid reaches the required level, switch SW1 opens and de-energizes relay R2, turning off the pump. When the fluid in the tank is used and the level drops, SW1 closes and pumps fluid to replace what has been used. The normal operation of the system is the switch SW1 opening and closing to turn off and turn on the pump *via* relay R2.

As a safety feature, the second level sensor, L2, is connected to switch SW2. When the fluid level is unacceptably high, SW2 opens and de-energizes relay R1. R1 contacts then open to break the control circuit. This results in R2 de-energizing; its contacts open, removing power from the pump. This would then require a manual restart.

For the system failure mode “tank overfills”, the relevant component failure modes along with the failure rate and repair time data are shown in Table 1. Some of the failure modes are revealed, such as, when relay R2 contacts get stuck and remain closed.

This component condition would mean that the pump keeps running and the problem is revealed by the tank overfilling. Its probability of failure is given by equation (1), where the repair rate is given by the reciprocal of the mean time to failure. Other components, such as relay R1 contacts failing closed are unrevealed, as this is the normal operating state for that component. All of the component failure modes associated with the safety system remain unrevealed, as for this class of events, the failure is revealed only when the component is tested/inspected or when a demand for the component to work occurs. For these component failure events, an inspection interval of 6 months (4380h) is assumed, which enables the probability of the event to be calculated as in equation (2).

The fault tree developed for the undesired top event “tank overfills” is illustrated in Figure 3. The text boxes specify exactly what each gate output event in the fault tree represents. Each branch is developed downward using only AND and OR gates until basic events (component failure events) are encountered and the failure causality development is terminated.

Figure 4 Simple tank level control system

Table 1 Component failure modes and data

Component	Failure mode	Code	Failure rate (h^{-1})	Mean time to repair (h)
Push button	Stuck closed	PB	5×10^{-5}	2
Relay contacts	Stuck closed	R1/R2	6×10^{-5}	10
Switch	Stuck closed	SW1/SW2	5×10^{-5}	10
Level sensors	Fail to indicate high level	L1/L2	2×10^{-6}	5

The final fault tree structure, showing how the basic events combine to cause the system level failure event, is illustrated in Figure 5. In this fault tree, the component failure events appear only once in the structure. Large fault trees, developed for real systems, commonly feature multiple occurrences of basic events in the structure.

Manipulating the Boolean equation for the top event [3] yields the minimal cut sets of the fault tree. For the tank level control system fault tree, the complete list of minimal cut sets are given in Table 2. As can be seen, there are nine failure combinations in all. One is first order (a single event causes system failure), and eight are of order two.

Using the component failure data in Table 1, the system failure parameters can be calculated as

follows:

$$\text{Top event probability} = 7.5 \times 10^{-4}$$

$$\text{Top event frequency} = 7.72 \times 10^{-5} \text{ h}^{-1}$$

If the system failure predictions indicate an unacceptable performance, the weaknesses can be identified using component importance measures. The Fussell–Vesely measure is indicated in Table 3. The Fussell–Vesely measure of importance for each component is the proportion of the system failure probability that is caused by a minimal cut set which contains the event, divided by the total system failure probability, i.e., the probability of the union of the minimal cut sets containing the event divided by

Figure 5 Tank overfill fault tree structure

Table 2 Minimal cut sets

1	R2
2	SW1 PB
3	SW1 R1
4	SW1 SW2
5	SW1 L2
6	L1 PB
7	L1 R1
8	L1 SW2
9	L1 R1

Table 3 Importance measures

Rank	Component	Fussell–Vesely
1	R2	0.781
2	SW1	0.215
3	R1	0.080
4	SW2	0.068
5	PB	0.067
6	L1	0.004
7	L2	0.003

the system failure probability. The importance analysis shows that component R2 provides the biggest contribution to system failure.

The system assessment results presented have been obtained using commercial software [9].

State Space Methods

State space models (*see* **Extreme Event Risk; Digital Governance, Hotspot Detection, and Homeland Security**) identify all possible states in which a system can reside over its lifetime and predicts the probability of its being in each of these states. The system states are usually defined by identifying which of the components are functioning or failed. By examining the component conditions and determining the state of the system, each state is then labeled as a system functioning state or a state in which the system has failed. Having performed the analysis and determined the likelihood of the system being in each state, the system performance prediction is then a matter of adding the relevant state probabilities.

System reliability modeling requires that the states identified for the system must include every possibility (exhaustive) and that the system must only be able to reside in one state at any time (mutually exclusive).

For a Markov approach to be valid two assumptions have to be appropriate:

- The system lacks memory.
- The system is homogeneous.

For the system to be memoryless, it means that the immediate future of the system is governed by its current state. The history of how the system got to reside in its current state is of no consequence. So if we consider the state X_k that the system is in at discrete-time points 1, 2, ..., k , where k is its current state, then

$$P(X_{k+1}|X_k, X_{k-1}, X_{k-2} \dots X_1) = P(X_{k+1}|X_k) \quad (10)$$

For the system to be homogeneous, it means that if it is in any state, the likelihood of moving from this state to any other does not change over time. Hence the transition probabilities or occurrence rates are constant.

Markov analysis is a state space technique commonly used for system reliability modeling. While being discrete in state space, it can be either continuous or discrete with respect to the time domain and both have applications to systems reliability.

Markov models (*see* **Reliability Optimization; Optimal Stopping and Dynamic Programming**) are of particular relevance while modeling the reliability of a system in which some aspect of its design, operation, or maintenance introduces dependencies amongst its components. Typical examples of this

are standby systems and systems in which failed components frequently have to queue for repair. Standby systems feature an operational, or primary component, and a backup, standby, component that is brought into operation to replace the primary component when it fails. For standby situations, the failure characteristics of the backup component can be dependent on the performance of the primary component. When the primary component fails, the backup component becomes operational, and its likelihood of failure increases. To provide greater insight into the method, a Markov model for the warm standby situation is discussed in the next section.

The two Markov approaches, discrete and continuous, are now considered separately.

Continuous-Time Markov Models

An example of a continuous-time Markov model (see **Multistate Models for Life Insurance Mathematics**) is shown in Figure 6. It represents the warm standby system with two identical repairable components A and B. One acts as the operational component at which point the other component acts as its standby. As can be seen, there are five nodes on the model, each representing a different state in which the system can reside. The system states are defined in terms of the states of the two components A and B, which can be operational (O), standby (S), or failed (F). Assume also that the failure rate of both components is λ when operational and $\bar{\lambda}$ when in standby. The rate at which either component is repaired when failed is ν . The five states included in the model are all mutually exclusive so that the system can only reside in one of the alternative states at any one time, and they represent all possible conditions of the system. The states are labeled 1–5 for identification purposes.

The transitions between the states occur when the conditions of the components, and therefore, the system, change due to the occurrence of a failure or repair. Assume that the initial condition of the system is that component A is operational and component B is in standby, state 1 in Figure 6. This situation can change in two ways: the operational component can fail with rate λ , which causes the backup component B to become operational and the failed component to undergo repair (state 3), or the backup component can fail with rate $\bar{\lambda}$, instigating its repair (state 4). The first of these situations is indicated on the Markov

Figure 6 Continuous-time Markov model for a two-component warm standby system

state transition diagram with an arrow (directed edge) from state 1 to state 3, with associated value of λ . The second transition is indicated by an arrow from state 1 is to state 4, with associated value $\bar{\lambda}$.

Only when both components A and B are in the failed state does the system fail. This is represented by state 5 on the Markov model. To determine the availability of the system, it is required to calculate the probability that the system is in the state represented by node 5 on the diagram.

The behavior of the system is represented by a set of first-order linear differential equations which are in matrix form.

$$[\dot{Q}] = [Q] \cdot [A]$$

where $[Q] = [Q_1(t), Q_2(t), Q_3(t), Q_4(t), Q_5(t)]$

$Q_i(t)$ is the probability of being in state i at time t

and $[A] =$

$$\begin{bmatrix} -(\lambda + \bar{\lambda}) & 0 & \lambda & \bar{\lambda} & 0 \\ 0 & -(\lambda + \bar{\lambda}) & \bar{\lambda} & \lambda & 0 \\ 0 & \nu & -(\lambda + \nu) & 0 & \lambda \\ \nu & 0 & 0 & -(\lambda + \nu) & \lambda \\ 0 & 0 & \nu & \nu & -2\nu \end{bmatrix} \quad (11)$$

Note that expressing the equations in this form makes the matrix $\mathbf{A}$ very easy to construct. The off-diagonal terms in row i column j represent the transition rate from state i to state j . The diagonal terms are then calculated so that every row sums to zero.

The solution of the equations yields the time-dependent probabilities of the system residing in each of the states. The system availability is then obtained by summing the probabilities of its being in each of the states that correspond to the system working. Summing the system failure state probabilities gives the system unavailability. Depending on the method employed to solve the equations, time-dependent or steady-state solutions can be obtained.

For some systems, particularly those whose failure may result in fatalities, the requirement is to operate without failure over a period of time. For such systems, it is more appropriate to calculate their unreliability rather than their unavailability. Since system failure cannot be tolerated, the Markov model for the system is modified so that when a system failed state is entered, it cannot make a transition back to a system functioning state. To do this, the transitions that return any system failed state to a state in which the system functions (usually as a result of repair), are removed. This makes the system failed states *absorbing*. Solution of the equations resulting from this model give the system unreliability.

The Markov method is a very flexible technique for system reliability modeling. Its advantage is the ease with which it can accommodate dependencies within the model. For it to be an appropriate technique to use, it does, however, require that the Markov property holds and as a consequence, the failure and repair rates do not vary with time. As such, *wear-out* (increasing failure rate) and *burn-in* (decreasing failure rate) cannot be accommodated. It is also unusual for repair times to be governed by a random process, as implied by the exponential distribution. From a practical viewpoint, a difficulty can arise by the model size for medium to large systems, as the Markov model size increases exponentially with the number of components in the system.

Discrete-Time Markov Models

For discrete-time Markov models, the representation of the states in which the system can reside remains

the same as in its continuous-time counterpart. However, the system state is considered at the end of specified, discrete, time periods, and the values associated with the edges represent the probability of moving from one state to another in this period. An example of a discrete-time Markov model is shown in Figure 7. The number associated with each arc joining the nodes is the probability that in the time period the system moves from the state at the start of the arrow to the state that the arrow points to.

The equations that govern the probability of being in each state after n time periods $Q(n)$ are given by

$$[Q(n)] = [Q(0)][B]^n$$

$$\text{where } [Q(n)] = [Q_1(n), Q_2(n), Q_3(n)]$$

$[Q(0)]$ is the initial state probability vector

$$\text{and } [B] = \begin{bmatrix} 1 - P_1 & P_1 & 0 \\ 0 & 1 - P_2 & P_2 \\ P_4 & P_3 & 1 - P_3 - P_4 \end{bmatrix} \quad (12)$$

Like the continuous-time Markov models, the equations in this form are easily formed. For the matrix $\mathbf{B}$, each off-diagonal term in row i column j is the probability of moving from state i to state j in the discrete-time period considered. The diagonal terms are then calculated to make the rows sum to one and represent the probability that the system remains in that state over the time period.

Solution methods can yield either transient or steady-state probabilities of being in each state,

Figure 7 Discrete-time Markov model

as appropriate. For system unreliability prediction, the model is changed to make failed system states absorbing.

Simulation Methods

Monte Carlo Simulation

At times, the characteristics of a system can mean that the assumptions required for the analytical approaches such as the combinatorial or state space methods are not appropriate. There may be, for example, complex dependencies between components in the system or component failure time or repair time distributions of a form that makes the mathematics to predict failure probabilities complex or impossible to perform in a closed form. An alternative, highly flexible method, is Monte Carlo simulation (see **Global Warming; Risk Measures and Economic Capital for (Re)insurers; Simulation in Risk Management; Uncertainty Analysis and Dependence Modeling**). This is a process by which the system behavior is run as an experiment, conducted on the computer. Event times are randomly sampled from the appropriate event distributions. The system structure and operational conditions then determine when the system failure occurs. A single pass through the simulation is governed by the appropriate probability distributions and represents one possible set of events and outcome we could achieve, if we were to operate the system. We need to conduct the experiment a large number of times to get statistically significant results. This process delivers far more detail than just a point estimate of system parameters: we can get distributions of times to system

outcome events. The likelihood of system performance characteristics can be determined as a relative frequency, i.e., the number of simulations that resulted in this outcome divided by the total number of simulations. Because of the large number of simulations that are generally required for the system reliability characteristics to converge, a computer tool is essential for this method to be a practical proposition.

As an example of how simple the simulation concept is, consider a two-component parallel system whose components fail with a fixed probability. Assume the two components, labeled A and B, have failure probabilities 0.1 and 0.05, respectively.

The simulation of the system requires the state of each component to be established. This is achieved using random numbers in the range $[0,1]$. If a number within this range is generated randomly, then all numbers are equally likely. Consider the unit lines for each of the two components shown in Figure 8.

The first component has a 0.1 chance of failure. The chance that a random number generated lies in the range $[0,0.1]$ is 0.1. Therefore, if the random number generated lies in this range the component A is considered to be failed for this particular simulation. A random number in the range $[0.1,1.0]$ would indicate component functionality. For the simulation illustrated, the random numbers have resulted in the failure of component A and the functioning of component B. Since the system is a parallel structure, it continues to be operational with component A failed. This provides one simulation. Repetition of the experiment many times would be required to provide an adequate indication of the expected system performance.

Figure 8 Simulation example – fixed probabilities

More complex system simulations require random samples to be taken from probability distributions representing the time at which events occur. The method used to do this depends on the form of the probability distribution [10]. A process, which works for some distributions, is the inverse transformation method. In this case, a random number is generated that lies in the range $[0,1]$. This variable has the same properties as the cumulative failure probability distribution $F(t)$. Therefore, by generating the random number and equating it to the cumulative probability, the time, t , at which the event occurred can be generated (see Figure 9). Times, generated in this way, conform to the distribution. Where the closed form of the distribution (such as for the exponential and Weibull) can be inverted, this method can be used.

Consider the exponential distribution with failure rate parameter λ given by

$$F(t) = 1 - e^{-\lambda t} \quad (13)$$

Equating $F(t)$ to a random number X in the range $[0,1]$ and rearranging (noting that $1 - X$ is also uniform on $[0,1]$), gives a random sample from this distribution.

$$t = -\frac{1}{\lambda} \ln X \quad (14)$$

Consider a two-component parallel system with identical components, A and B, both with failure rate $1 \times 10^{-4} \text{ h}^{-1}$. Using two random numbers, 0.456 and 0.778, to generate the failure times for A and B,

Figure 9 Inverse transformation sampling method

respectively, gives

$$\begin{aligned} t_A &= -\frac{1}{1 \times 10^{-4}} \ln 0.456 = 7853 \text{ h} \\ t_B &= -\frac{1}{1 \times 10^{-4}} \ln 0.778 = 2510 \text{ h} \end{aligned} \quad (15)$$

A parallel, fully redundant, system of nonreparable components works until the last component fails, i.e. for a two-component system, the system failure time $t_{\text{sys}} = \max(t_A, t_B)$. The last component failure time for this particular simulation is 7853 h.

For a series system made of nonreparable components, the failure time for the system is the minimum of the failure times for the components.

Monte Carlo simulation is a very flexible means of modeling the system behavior. No assumptions are required by the analyst, and the difficulty of its implementation is in developing an efficient housekeeping routine to keep track of the events and the system status as the simulation progresses. The disadvantage of the method is the large amounts of simulations that are required to get meaningful statistics on the system performance. For example, consider a system of n components. If the system is such that its actual failure probability was 10^{-4} , then it would need $n \times 10^4$ random samples from probability distributions to be generated before we could expect to produce one system failure event.

Petri Nets

Petri nets (PNs) [11] (see **Human Reliability Assessment, Markov Modeling in Reliability**) are an adaptable and versatile graphical modeling tool used for dynamic system representation. A PN is a bipartite directed graph with two types of node: *places*, which are circular, and *transitions*, shown as bars or rectangles (Figure 10). Places link only to transitions, and *vice versa*, using directed arcs. It is possible for a

Figure 10 Transition enabling and switching

place to have several arcs to or from the same transition, which is condensed down into a single arc with a *weight* or *multiplicity*, denoted by a slash through the arc with a number next to it. If there is no slash, the multiplicity is assumed to be 1. The dynamic aspect of the PN is formed by *tokens* or *marks*, which abide within places, and are passed between them by the *switching* of transitions.

Figure 10 shows a transition that has three places as inputs. The first place has an arc weight of 2, the middle one has a multiplicity of 1, while the third has a weight of 4. Because the number of tokens in all of the input places to the transition contains at least the weight-number of tokens, the transition can be said to be *enabled*. Transitions can also be associated with a delay, which forces the transition to postpone switching for a period after being enabled. This delay can be zero or randomly sampled from a given distribution. In Figure 10, there is a time delay of t applied once the transition is enabled. Once the time period has passed and the transition remains enabled, the switching takes place. This process removes the number of tokens in each input place corresponding to the multiplicity of the relevant arc, and “creates” the weight-number of tokens in each output place. This is shown in Figure 10 where the switching removes two, one, and four tokens from each of the input places, and deposits three tokens in the output place. The transition is then disabled, as the input places do not have the correct number of tokens.

It is possible to prevent a transition switching by using an *inhibitor arc*. This special arc, shown by a line with a small circle on the end instead of an arrow, connects only an input place to a transition (see Figure 11). It acts such that if the number of tokens within the place is at least that of the arc weighting, the transition cannot switch, regardless of whether it is enabled or not. In Figure 11, the

Figure 11 Inhibitor arc preventing switching

otherwise enabled transition can wait for time t to expire, but cannot switch – no tokens are moved by that transition, while the inhibiting place contains the relevant number of tokens.

It is the switching of the transitions that represents the dynamic behavior of the PN model – the ability to transport tokens around the net, thereby changing the *marking* with each switch. The *net marking* is a term given to the distribution of the tokens throughout the whole PN, and each of its forms represents a different system state. This is what is of interest to the analyst.

As a simple illustration of how the PN can be used to model system states, consider the PN shown in Figure 12. This represents a two-component parallel system in which the components A and B are both repairable. Initially, the system has both A and B working, and these states are marked with tokens (as shown). The failure and repair times of the components are F_A , R_A and F_B , R_B . With the input places to transitions 1 and 3 marked, then after F_A and F_B , respectively, these transitions will fire. When transition 1 fires, it removes the token from place 1 and puts tokens in the output places 2 and 5. Should component A then be repaired, by the firing of transition 2, this removes the token from places 2 and 5 and puts a token in place 1. The failure and repair of component B is modeled in the same way. It is only when both components have failed that there are two tokens in place 5, which then fires immediately (zero delay) and places a token in place 6, which represents the system failed state.

Event Tree Analysis

Event tree analysis is a method which forms the cornerstone of many risk assessments. It differs from techniques such as fault tree analysis in that it is an inductive rather than deductive approach and takes into account all possible consequences that can result following the hazard.

An event tree has its branches spreading from left to right across the diagram, an example of which is illustrated in Figure 13.

The event on the far left is known as the initiating event and usually represents the occurrence of a hazard. On the rest of the diagram, each column represents an event which influences the outcome that results following the occurrence of the hazard. Commonly, each column represents a system that is

Figure 12 Petri net for a two-component parallel system

designed to respond to the hazard. Within that column, the branches correspond to the success or failure of the system; or a null branch, which means that the system success or failure, given the events which have happened before it, is irrelevant in determining the consequence. For instance, in the small example illustrated in Figure 13, the initiating event is a gas release. In these circumstances, there are three systems that are designed to respond to this hazard. A gas detection system that would establish that the release has occurred, and two systems triggered by the detection system. The first is an isolation system that isolates and shuts down the process, the second is a blowdown system to depressurize the gas line. Both of these measures are designed to limit the quantity of gas that can be released. The gas release event is the event represented on the first single left hand branch. The three systems that are designed to respond to this event are then considered in the order that they operate in the next three columns. The detection system is considered first in the second column. The two branches passing through this column represent the success (top

Figure 13 Event tree example

branch) and failure (bottom branch) for this system. In the next two columns, the functionality of the isolation and blowdown systems are considered. All combinations of success and failure of these systems are represented. Following the failure of the detection system, the isolation and blowdown systems are not activated, and so the branch that passes through the columns representing the functionality of these systems is a null branch, since the functionality of these systems is irrelevant in determining the final outcome.

Having constructed the event tree diagram, all possible responses to the hazard have been identified. Each response is represented by the end points of the branches on the far right of the diagram. For example, in Figure 13, the sequence of events labeled 1 at the top of the outcomes represents the situation in which all three systems have responded, as intended, to the hazard. The next two outcomes represent the correct functioning of the leak detection system, with only one of the isolation or blowdown systems responding. Sequence, outcome 4, has the detected leak being neither isolated or blowdown. The final outcome has the detection system failed, and so there is no response to the leak.

All outcome events have an associated consequence, C_i , indicated in a column at the end of the event tree diagram. The consequence depends on the nature of the hazard and can be expressed in terms of quantities such as: financial loss, injuries, fatalities, environmental damage, or the magnitude of a nuclear release.

Quantification of the event tree diagram produces the frequency of each of the outcome events, f_i . The data required to determine this is the frequency of the initiating event, and the probability of progressing along each of the branch points represents the failure or functionality of each of the systems included on the diagram. The failure of each system can be determined by any of the other methods discussed in this article, depending on the characteristics of the system concerned. Fault trees are, however, the most commonly used technique for this purpose. The event tree shows all possible responses to the initiating event and so, when quantified, the total of the frequencies for each of the outcome events will sum to the frequency of the initiating event.

The results from an event tree analysis can be represented in many forms. The total risk can be

determined from

$$Risk = \sum_{i=1}^n f_i C_i \quad (16)$$

where f_i and C_i are the frequency and consequence, respectively, of each of the n branch outcomes.

The results can also be represented graphically as a plot of consequence (severity) against frequency. It is common to use log scales on the axes of such a plot. Also, the most common form to express the results is as a cumulative frequency versus severity plot, where the cumulative frequency is the frequency by which the associated severity level is exceeded.

Summary of When to Use Each Method

With the choice of possible methods available to conduct an assessment for any given system, it has to be decided which one to select. The selection depends on the characteristics of the system and the performance parameter which is to be predicted. The list of possible methods is of those whose implicit assumptions are appropriate to model the system. From this list, the method selected would be the one that provides the most efficient analysis. Figure 14 shows the relationship between complexity and efficiency of the systems reliability techniques discussed. The most efficient techniques are placed on the left of the diagram. As the line moves from left to right, this indicates increasing complexity of the techniques associated with decreased efficiency. As such, the preferred method would be the method located as far to the left as possible of the diagram, which has the capability to model the system parameters of interest and whose assumptions are appropriate to model the system structure, operation, and maintenance.

If the requirement is to model the system unavailability or failure rate, then all methods can be used. The combinatorial methods on the left extreme of the diagram would be the preferred option. For these methods to be appropriate, the component failures must be independent of each other, and the component failure and repair rates must be constant (an implementation limitation of most of the commercial codes). Under these circumstances, fault tree analysis or reliability networks can be used. Fault tree analysis is the preferred choice between these two options, since the text boxes in the diagram enable the analysis to be documented. This is a very useful

Figure 14 Characteristics of system reliability quantification methods

feature to explain the thinking behind the failure logic development to peers, managers, designers, and most importantly, regulators. When the assumption of independence cannot be made, then, if constant component failure and repair rates are appropriate, the Markov models can be used. In the event that the size of the system containing dependencies leads to a state space explosion, then either of the two simulation based approaches should be used.

If the system reliability is to be predicted, then the choices lie between the state space and simulation methods. The choice is again governed by the factors described in the previous paragraph.

In the situation in which the component failure or repair time distributions are not exponential, then the selection would be one of the simulation methods.

The above methods predict the probability that the system fails in terms of the likelihood of its component failures and the structure of the system. These predictions can then be incorporated into an event tree analysis to perform a risk analysis of the system.

Threshold Models

What is a Threshold Model?

Dose–response models (*see Dose–Response Analysis*) link the dose of an agent, d , to the effect observed in the organism it is administered to. The shape of dose–response at low doses is of considerable interest because exposure of humans to carcinogens is usually orders of magnitude below the dose level used in bioassays. A *threshold model* focuses on the low-dose behavior of dose–response models and assumes that doses below a threshold, d^* , do not have an effect on response, i.e., doses below d^* lead to the same response as background. Specifically in cancer risk assessment, for example, response is often considered as lifetime tumor probability. Mathematically, a general threshold model for the effect probability $P(d, t)$ in observational period t is given by Edler and Kopp-Schneider [1]

$$P(d, t) = \begin{cases} p_0(t) & \text{if } d \leq d^* \\ p_0(t) + (1 - p_0(t))F(d, d^*, t) & \text{if } d > d^* \end{cases} \quad (1)$$

where $p_0(t)$ denotes the background response and $F(d, d^*, t)$ represents a continuous – usually monotonically increasing – function with values between 0 and 1 and $F(d^*, d^*, t) = 0$. Usually t is considered as fixed. Schematically, a threshold model is visualized in Figure 1.

Dependence of $P(d, t)$ on the observation period is often neglected. This may be justified in typical bioassays with e.g., a 2-year duration. However, variations in observation period will lead to alterations in dose–response relationship and obviously also in potential threshold doses. Equation (1) and Figure 1 show a strict threshold. Less stringent definitions of threshold models have been discussed, requiring that the derivative with respect to dose, $\partial P(d, t)/\partial d$, be zero at $d = 0$. This definition requires that dose–response starts horizontally in dose 0, leading to a curve with a shape similar to Figure 1. All polynomials of order >1 show this property. However, no clear-cut threshold dose can be defined whenever the derivative is positive for positive dose.

Why Were Threshold Models Introduced?

The motivation for introducing the threshold concept is as follows. If threshold doses existed and could be estimated, safe exposure levels could be derived, leading to tolerable small exposures. In this case, exposure below the threshold dose would be acceptable and no further endeavor is necessary to reduce exposure. On the other hand, efforts to reduce exposure in the environment to extremely small values are justified if dose–response models do not exhibit a threshold. Hence, the existence or nonexistence of thresholds has tremendous consequences for practical risk assessment. As a result, the existence of thresholds for cancer risk models has been a matter of fierce controversy.

The observation that organisms in a bioassay or epidemiologic study receiving a positive dose show no statistically significant difference in response compared to background may be taken as argument for the existence of an apparent threshold. However, the absence of a statistically significant effect depends on bioassay sample size and therefore, study power. Lack of evidence for a significant effect may not be interpreted as evidence for the lack of the effect. Apparent thresholds may also be observed depending on the choice of the scale when plotting dose–response curves: linear dose–response curves may show a thresholdlike behavior as depicted in Figure 1 if dose is plotted on a logarithmic scale [2].

Do Threshold Doses Really Exist?

Theoretical arguments have been collected to support the existence of thresholds. Possible threshold mechanisms include metabolic inactivation of the compound, DNA repair, cell cycle arrest, apoptosis of damaged cells, and control of the immune system [3]. The discussion about the existence of thresholds is closely related to the discussed distinction between genotoxic and nongenotoxic carcinogenic compounds. The existence of thresholds for nongenotoxic agents (e.g., tumor promoters) is more or less accepted in the scientific community, whereas genotoxic compounds have usually been associated with a nonthreshold behavior. In this context, it has recently been suggested that two types of threshold should be distinguished. Dose–response

Figure 1 Schematic dose–response relationship with threshold dose d^* for fixed observational period t

of nongenotoxic carcinogens as well as some genotoxic agents acting as e.g., mitotic spindle poisons, may show a “perfect” threshold. Definition of a “practical” threshold is based on the idea that the chemical should cause no genotoxic effect at very low exposure levels owing to e.g., rapid degradation or other factors that limit target exposure. Using this definition of thresholds, it has been suggested that carcinogens can be classified in the following way [4, 5]: (a) nonthreshold genotoxic agents; (b) genotoxic compounds for which the existence of a threshold is possible, but is not yet sufficiently supported; (c) genotoxic carcinogens for which a “practical” threshold is supported by studies on mechanism and/or toxicokinetics; (d) genotoxic carcinogens for which a “perfect” threshold is associated with a no-observed effect level; and (e) nongenotoxic carcinogens for which a “perfect” threshold is associated with a no-observed effect level.

However, even if a threshold exists, determination of its actual value, d^* , may be hampered by practical problems. Estimation from study data involves the

issues of choice of doses, sample size, and study power. It should be noted in this context that the no-observed adverse effect level (NOAEL) has been taken as surrogate for threshold dose.

Toxic Torts: Implications for Risk Management

This article introduces aspects of the law of torts that relate exposures to noxious agents (possibly due to either willful or negligent conduct), to their possible adverse effects. Tort law is a form of civil (not criminal) law that intervenes to redress wrongs from willful or negligible behavior and compensate (generally with money awards) those legally proved injured by those actions. In those cases, law and science intersect at the key issue of causation: scientific evidence and proof of causation must fit within concepts of legal causation. All of these use elements of scientific evidence and causal reasoning that are part of quantitative risk assessment methods. In particular, concepts such as increased risk, dose–response, statistical significance and inference, and probabilistic reasoning are essential. Examples from the United States, United Kingdom, and Australia illustrate differences among jurisdictions and modern views of the interactions between science and law.

Toxic tort law concerns past and, in some limited instances, feared future injuries from exposure to toxicants and carcinogens generally produced, emitted, or disposed in ways that (are alleged to) contravene certain social norms that constitute the current law of torts. (For brevity, this article does not address injunctive relief and intentional torts such as assault and battery.) In tort law, the scientific evidence concerning human health generally consists of epidemiological studies, although animal studies (such as those conducted with rodents – see **Cancer Risk Evaluation from Animal Studies**) and tests on lower organisms (e.g., bacteria) may also be considered. Establishing causation based on these heterogeneous data, and often competing etiological theories, requires abstractions and reasoning with probabilities, instead of relying on deterministic certainty. Cranor [1] provides the detail of some of the methods used to develop evidence *via* a “weight-of-evidence” system to show causation in regulatory law.

To deal with these complications, the law uses seemingly objective legal tests of causation, asking whether the defendant’s acts were a “substantial factor” producing injury, or whether, “but for” the defendant’s actions, the plaintiff would not have

suffered injury. The former compares the extent and importance of the defendant’s tortious activity in causing harm with other known and unknown causes, but it is too subjective to produce predictable results in most toxic exposure cases. The latter deterministically limits evaluation of causal factors to one – it seeks to answer whether “but for the act of the defendant, the plaintiff would not have been injured”. However, often such deterministic tests are too limiting in toxic tort and environmental law. For instance, in *Allen et al. v. U.S.* (588 F.Supp. 247 (1984), rev’d on other grounds, 816 F. 2d 1417 (10th Cir. 1988), cert. den’d, 484 US 1004 (1988)), several plaintiffs brought action against the United States under the Federal Torts Claim Act, attempting to recover for leukemia alleged to be the result of exposure to atomic bomb fallout after those weapons were tested in Nevada. The trial court discussed tests such as “natural and probable” consequences, “substantial factor”, and “more likely than not”, finally opting for the “substantial factor” test, rather than “but for”. The *Allen* court held that each plaintiff should meet at the “preponderance of the evidence” level the burden of proof. The probability of exposure to fallout resulting in doses in significant excess of “background” was predicated on the following basis:

1. injury consistent with those known to be caused by ionizing radiation; and
2. residence near the Nevada Test Site for at least some, if not all, of the years when the tests were conducted.

Reading tort law cases produces other terms of art used to assess what is known about the adverse effects of toxic exposures. For example, in the case *Smith v. Humboldt Dye Works, Inc.* (34 App. Div. 2d 1041 (1970)), the court held that 25 years of exposure to “known” carcinogens that were causally linked with bladder tumor were a “substantial evidence” of causality, even though the scientific evidence was in conflict and the statistical results unclear. Also in the United States, the Restatement Second of Torts (Restatement (II) Section 431, comment (a)) uses “legal cause”, rather than “proximate cause”, predicated on determining whether a tortfeasor’s act constitutes a “substantial factor” (*In Re Bendectin Litigation*, 857 F2d. 290 (6th Cir. 1988)), in bringing about a result, considering, *inter alia*, the “number of factors” in the causal structure, the conduct of the defendant in creating or setting

in motion forces leading to injury, those factors that go beyond the responsibility of the defendant, the time lag, and foreseeability between cause and effect [2].

Regarding the duty of care (the legal duty from the defendant to the plaintiff, which is an essential element to be proved in a tort law case) to warn consumer of potentially hazardous exposures (i.e., voluntarily taken vaccinations), in *Davis v. Wyeth* (399 F. 2d 121 (9th Cir. 1986)), the court held that a duty to warn (for the manufacture defendant) exists even though the probability of contracting poliomyelitis from being vaccinated was one in a million (but it apparently did happen to the plaintiff who contracted polio and thus sued the manufacturer).

In reading this article, key questions to keep in mind include the following: (a) what is the probability that the defendant's act caused harm to the plaintiff; (b) what is the probability that the plaintiff is among those harmed; and (c), given the answers to (a) and (b), what should be done to compensate the plaintiff properly?

Causation in Tort Law

A Snippet of History: How to Establish Legal Causation?

In the United Kingdom, cause has been assessed under different terms of art, from "real effective cause" to "direct" cause to the cause that was "natural and probable" to "proximate cause". These causal descriptions culminated with *Overseas Tankship (UK) Ltd v. Morts Dock and Engineering Co. Ltd. (The Wagon Mound)* ([1961] A. C. 388), in which "direct consequence" was disapproved, and was replaced by the "reasonable foreseeability" of harm in *Wagon Mound No. 2 (Overseas Tankship (UK) Ltd v. The Miller Steamship Co Pty* [1967] 1 A. C. 617). The dissent by Andrews J., in *Palsgraf v. Long Island RR* (162 N.E. 99 (N.Y. 1928)) defines "proximate cause" as follows: "What we do mean by the word 'proximate' is, that because of convenience, of public policy, of a rough sense of justice, the law arbitrarily declines to trace a series of events beyond a certain point. It is all a question of expediency". Moreover, "[t]he foresight of which the courts speaks assumes prevision".

A more recent case, *Lee v. Heyden (Pamela Lee B. v. Heyden*, 94 C.D.O.S. 4265 (1994)) summarizes causation as follows:

[t]he causation element is satisfied when the plaintiff establishes (1) that the defendant's breach of duty (...) was a substantial factor in bringing about the plaintiff's harm and (2) there is no rule of law relieving the defendant's of liability.

In England, Lord Reid, in the case *McGhee v. National Coal Board* ([1973] 1 WLR 1, at 5) stated as follows:

... it has often been said that the legal concept of causation is not based on logic or philosophy. It is based on the practical way in which the ordinary man's mind works in the everyday affairs of life.

In Australia, in *Bennett v Minister of Community Welfare* ((1992) 107 ALR 617), the Australian High Court followed the majority in the earlier case *March v. E & MH Stramare Pty Ltd* ((1991) 171 CLR 506), holding as follows:

In ... negligence, causation is essentially a question of fact, to be resolved as a matter of common sense. In resolving that question, the "but for" test, applied as a negative criterion of causation, has an important role to play but it is not a comprehensive and exclusive test of causation; value judgments and policy considerations necessarily intrude.

In light of these admonitions, consider an environmental or occupational case in which the empirical evidence is epidemiological. The plaintiff demonstrates "general causation" by showing a statistically significant increase in the relative risk. In *Usury v. Turner Elkhorn Mining Co.*, 428 U.S. 1 (1976), the US Supreme Court held that uncertain causation does not bar *statutory* recovery. And, a negative finding in a radiological examination does not suffice to deny a worker's compensation claim. *Usury* holds that Congress can develop *probabilistic* health protection standards and provide just compensation in the factual instances of uncertain etiological factors associated with dreaded, fatal, and causally complex diseases.

More recently, in *James Mitchell et al. v. Jose L. Gonzales et al.* (54 Cal. 3d 1041; 819 P.2d 872; 199; 1 Cal. Rptr. 2d 913), the Supreme Court of California disapproved the "'but for' test of cause in fact" ruling in favor of the "substantial factor" test, further illustrating the pathology of causation

in legal reasoning. The issue before the Supreme Court of California concerned the instructions to the fact finder about *factual causation*. According to this court, *proximate cause* contains *cause in fact* or actual cause; this is the scientific aspect of legal causation. Yet, using the phrase *proximate cause* to satisfy both factual and legal causation has and continues to generate much confusion. Thus, in *Mitchell*, the Supreme Court of California cited Prosser's (1950) statement "that 'proximate cause' . . . is a complex term of highly uncertain meaning under which other rules, doctrines and reasons lie buried . . .". For jury instruction, according to Charrow [3] "the term *proximate cause* was misunderstood by 23% of the subjects . . . They interpreted it as 'approximate cause,' 'estimated cause,' or some fabrication". The "substantial factor" test applies when there are concurrent (not necessarily jointly necessary and sufficient) causal events such that applying the "but for" test would result in both defendants escaping justice. Prosser [4] declared the *substantial factor* test "sufficiently intelligible to any layman to furnish an adequate guide to the jury, and it is neither possible nor desirable to reduce it to lower terms". However, in the *Mitchell* case, the court never stated what it required, quantitatively, for a *factor* to be "substantial".

Legal Aspects of Causation: Foreseeability, Duty of Care, Proximity, and Relationship. The normal is typically the foreseeable. As the Supreme Court of California put it, "[o]n a clear day, some courts can see forever, at least when they are looking for negligence". In an earlier case, it had held that "[e]xperience has shown that . . . foresight alone [does not] provides a socially and judicially acceptable limit on recovery of damages for injury". Foreseeability limits tort liability by limiting the causal inquiry about the factual chain of events alleged by the plaintiff. In some cases, legal duty is a way out of the difficulties of setting legal bounds on causally complex facts. For example, in Australia, in *Chapman v. Hearse* ((1962), 106 C. L. R. 112), the Australian High Court held that "[u]nless all events which happened were reasonably foreseeable", Chapman was not guilty of a breach of his legal duty. The phrase "reasonably foreseeable" was not a direct test of causation; rather, "it marks the limits beyond which a tortfeasor will not be held responsible. . ." as the theoretical proposition that foreseeability limits legal duty.

If there is a duty, it must be related to physical cause so that the legal limit can be set with confidence. There is a one-to-one correspondence between foreseeability and this limit on the factual, but *ex post*, reconstructed view of factual causation. In the United Kingdom, *Caparo Plc v. Dickman* ([1990] 2 A. C. 605 (H. L.)), at 617–618) developed a legal test articulated in terms of the following:

Foreseeability of damage (which itself has a substantial history in case law),

Legal proximity or neighborhood (which also has a rich history of interpretation), and the

Fair, just and reasonable imposition of a legal duty.

The plaintiff does not need to show with accuracy *all* of the elements required by the "reasonably foreseeable" test. It is sufficient to show "injury to a class of persons of which the plaintiff was one" and that such injury "might reasonably be foreseen as a consequence" of the defendant's tortious act.

Justification of risk management policy choices requires developing the formal nexus between factual causation and the limits of "foreseeability" further. Formal probabilistic analysis may help in defining what should be considered "foreseeable" on theoretical and empirical grounds.

Balancing Adversarial Evidence at Trial: "The Balance of the Probabilities" and Similar Tests

In tort cases, the *reasonable* mind is given the task of deciding causation, often according to innate common sense, even in cases involving scientific evidence of the greatest complexity. In traditional tort law cases, a trier of fact who is "51%" convinced of causation allows recovery, and one who is "49%" convinced does not. The question thus arises: how can a combination of subjective notions of uncertainty and common sense causation meet the burden of proof?

The "More Likely than Not" Test

Plaintiffs in the United States, the United Kingdom, Canada, and Australia must prove their facts using the "more probable than not" standard, thus maximizing the expected number of correct civil decisions. The

prevalent American tort law balancing standard is alternatively stated as “the balance of probabilities”, “preponderance of the evidence”, “more likely than not”, and “51%”. These phrases are supposed to impose the same burden of proof on the parties; once one party’s evidence is greater than that of the other, that party prevails according to the all or nothing rule of traditional tort liability. The essence of the test (*In Re Agent Orange Product Liability Litigation*, 597 F.Supp. 740, at 835) is that even “if there near certainty as to general causation, if there were significant uncertainty as to individual causation, traditional tort principles would dictate that causation be determined on a case-by-case basis. . .”. Some courts have distinguished between degrees of scientific certainty and “legal sufficiency”, and some have held that a lesser standard should apply to scientific facts. Other courts shift the burden to the defendant and keep the “more likely than not” test. On occasions, a higher standard of proof than the “more likely than not” applies in civil litigation. The standard of proof may be altered for events characterized by severe consequences – such as cancer – even if they have low probability. The idea that the standard of proof should be adjusted so that “high probability” is commensurate with “what is at stake” (United Kingdom, *Khawaja v. Secretary of State for the Home Department* [1984] AC 74) has sometimes been rejected because of the difficulties confronting a plaintiff in meeting those standards, and a perception that any balancing more stringent than the “more likely than not” can be, *a priori*, unfair to the toxic tort plaintiff (Australia High Court, *Neat Holdings Pty Ltd v. Karajan Holdings Pty Ltd*. ([1992] 67 ALJR 170 at 171)).

The interpretation of the “more likely than not” test as a probability number has led to various strains of this legal standard. The “strong” version would not accept statistical measures of association between events without additional evidence of a “. . . direct and actual knowledge of the causal relationship between the defendant’s tortious conduct and the plaintiff’s injury” [5]. The *Agent Orange* (597 F.Supp. 740, at 835) court has understood this to mean as follows:

... ‘proof that can provide direct and actual knowledge of the causal relationship between the defendant’s tortious conduct and the plaintiff’s injury’ is needed.

The “weak” version, on the other hand, suggests that statistical evidence alone can suffice to make a decision. Once the probabilistic balancing has taken place, the fact finder has a simple decision to make: either the balance of evidence has swung against the defendant, or it has not. Judge Weinstein echoed this view in stating that “particularistic evidence . . . is no less probabilistic than . . . statistical evidence.” His court favored the use of the “strong” version of the standard for individual plaintiffs, but appeared to support the “weak” version for class actions lawsuits (597 F.Supp. 740). For example, he noted that if 1000 cancers are expected and 1100 are found (and the result is statistically significant), then individual plaintiffs would never recover because $100/1100 = 9\%$ is below the conventional 51%. To avoid this patently unfair result for class action cases, Judge Weinstein proposed that results falling outside two standard deviations from the expected incidence of the disease, computed to be 31.6 excess cancers relative to the 1000 expected, should suffice to allow the more likely than not test to be met. The 100 excess cancers meet this new version of the more likely than not test. This test includes a reasonable measure of variability of the data, namely, the standard deviation, assuming – a strong assumption – that all plaintiffs are homogeneous with respect to exposure response.

An American tort law test that balances probability of harm against cost of mitigating that harm was enunciated by Judge Learned Hand, in *United States v. Carroll Towing Co.* (159 F.2d 169 (2d Cir. 1947)). This utilitarian formulation focuses on economic efficiency, assuming that the societal objective is to increase expenditures on safety measures until their marginal social cost equals the marginal social benefit. As Judge Learned Hand stated,

... the owner’s duty ... to provide against resulting injuries is a function of three variables: (1) the probability that she (the ship that caused initiated the sequence leading to damage) will break away; (2) the gravity of the resulting injury, if she does; (3) the burden of adequate precautions.

He then developed the formula for balancing these three variables as follows:

Possibly it serves to bring this notion into relief to state in algebraic terms: if the probability be called P, the injury, L; and the burden, B; liability depends upon whether B is less than L multiplied by P ...

In this formula, the expected (or average) value of the injury or economic loss controls. The cost can be either the “marginal” cost or the “average” cost.

Similarly, English law allows the balancing the magnitude of consequences against cost of reducing risk (*Edwards v. National Coal Board* ([1949] 1 KB 704)), while Australia defines reasonableness as the balancing of “magnitude of the risk and the degree of probability of occurrence along with the expense and difficulty and inconvenience of taking alleviating action and other conflicting responsibilities the defendant may have” (*Wyong Shire v. Shirt* (1980) 146 CLR 40).

What is, Legally, Good Science Regarding a Finding of Scientific Causation

Pretrial Admissibility of Scientific Evidence: Frye v. Daubert—Joiner—Kumho

The famous *Frye* standard for admissibility of scientific evidence based on what the court construes as being “generally accepted” in the relevant scientific community clashes with rapid scientific advances and the lag between new science and general acceptance. The *Frye* tests guard against false positives (especially in criminal cases, where proof must be “beyond a reasonable doubt” rather than merely by “preponderance of evidence”), but not against false negatives. Today, the increasing pace of information development and their contingency on newer information often makes *Frye* inappropriate for torts, although it persists in several states. The net effect of the rule is to exclude scientific evidence that could, nevertheless, be appropriate for the fact finders to consider. A version used in California (*Kelly–Frye*) seemingly reduces scientific opinions and findings by experts to a counting of the number of scientific peers proclaiming “yays” and “nays” and then deciding what correct causation is. However, Californian courts appear to limit *Kelly–Frye* to novel scientific methods and devices, such as DNA testing and voiceprint.

In Australia, in *R. v. Gilmore* [1977] 2 NSWLR 935 at 938–939), the following view was advanced (following a US case):

Absolute certainty . . . or unanimity of scientific opinion is not required for admissibility. ‘Every useful new development must have its first day in court . . .’

... Unless an exaggerated popular opinion . . . makes its use prejudicial or likely to mislead the jury, it is better to admit relevant scientific evidence . . . and allow its weight to be attacked by cross-examination and refutation

This “exaggerated popular opinion” is one of the two aspects of expert testimony that can lead to unfair results. The second aspect concerns ill-constructed expert testimony about causation. Expert opinion is generally given to assist the trier of fact (the jury, most of the time, or the judge in some situations), given all the other relevant evidences and various procedural constraints. This function argues for a formal and coherent balancing of the advantages and disadvantages of admission for both parties.

In the US federal system *Frye*’s hegemony ended in 1993 with the US Supreme Court case of *Daubert v. Merrell Dow Pharmaceuticals Inc* (509 U.S. 579 (1993)). The factors enumerated by the Supreme Court in *Daubert* include the following:

1. reliability (the empirical testing of scientific hypotheses or opinions that the expert intends to introduce as evidence);
2. scientific validity of the methods and reasoning and scientific peer review.

Daubert requires four factors to establish the reliability of *expert knowledge*: (a) a “theory or techniques . . . can be (and has been) tested”; (b) its “peer review and publication”; (c) its “known or potential rate of error” and “standards controlling the technique’s operation”; and (d) its “general acceptance in the relevant scientific community”. The context of the case determines the appropriate number of factors, reflecting the flexibility of the federal rules of evidence (FRE). Notably, *Daubert* places trial judges in the role of gatekeepers of scientific evidence:

The objective of this requirement is to ensure the reliability and relevancy of expert testimony. It is to make certain that an expert, whether basing testimony upon professional studies or personal experience, employs in the courtroom the same level of intellectual rigor that characterizes the practice of an expert in the relevant field.

The reach of *Daubert* was extended from scientific evidence to all expert evidence in *Kumho Tire Co., Ltd. et al. v. Carmichael, etc., et al.* (526 U.S. 137 (1999)). *Kumho* holds that *Daubert* applies to all contexts to which FRE 702 applies, regardless of whether scientific, technical, or other specialized knowledge

is introduced. The US Supreme Court confirmed in *Kumho* “judicial broad latitude” allowing gatekeeping by trial judges. Under *Kumho*, trial courts now determine the admissibility of expert testimony by analysis of the “reasonableness” of inference, and the expert’s methods for analysis and *whether those reasons lead to the conclusion derived*.

Standard of Review on Appeal: *General Electric Co. v. Joiner* (522 U.S. 136 (1997)). In *Joiner*, the US Supreme Court reconfirmed the trial judges’ considerable latitude in admitting scientific evidence of causation. The plaintiff’s experts advanced a theory of lung cancer causation based on cancer-promoting activity of PCBs in mice at high doses. One expert testified that it was “more likely than not that Mr. Joiner’s lung cancer was causally linked to cigarette smoking and PCB exposure”, and another testified that “lung cancer was caused or contributed to in a significant degree by the material with which Joiner had worked”. The plaintiff’s experts, however, would not testify that there was a “link between increases in lung cancer and PCB exposure among the workers they examined” on the basis of their own studies. They had used a “weight of the evidence” method to evaluate the causal relationship between Joiner’s exposure and his lung cancer. The evidence they considered included four epidemiological studies and animal bioassay results, as well as the plaintiff’s medical records. The PCB exposures in those studies were confounded by other agents, or the studies did not support a causal association, or PCBs were not mentioned in the exposures. After scrutinizing *some* of the epidemiological studies *individually*, as opposed to *aggregating* the evidence to get a better sense of overall results, the trial court (the federal district court) excluded that evidence. The court of appeal upheld this approach, finding that the studies did not provide sufficient evidence of a causal link to overturn the trial court findings of inadmissibility of the scientific opinions. The Supreme Court agreed with the trial court’s logic; it refused to accept expert *assertions* as a sufficient basis for admitting evidence.

Quantitative Risk Assessment, QRA, in Legal Causation

There is no satisfactory alternative to methods of QRA for developing sound causal arguments in toxic

tort law. Legal tests of causation require substantive quantitative and qualitative analyses to bound potential causation by accounting for likelihoods and expert opinion (perhaps encoded as prior probabilities or distributions, or as conditional independence relations in *influence diagrams*), to yield sound formulations of causation that combine both. Although qualitative aspects can be met by expert opinions, as *Daubert’s* “intellectual rigor” standard enjoins, methods of decision theory and QRA are also essential to understand and quantify potential outcomes of actions and to assess actions according to specific criteria of optimality for risk taking. QRA enables a correct, appropriately caveated understanding (expressly conditioned on available information) of the strength of a causal relation, and thus support and enhance legal causal analysis, regardless of the type of legal test used by a court.

Conclusions

Scientific causation can be crucial in determining legal causation using standards (such as *but for* or *more likely than not*) by which plaintiffs must legally demonstrate that the actions of the defendants (probably) caused their injuries. Courts in multiple countries use scientific causation and evidence in a much broader context by examining *reasonable* conduct, existence of *legal duty* and breach of such duty, *foreseeability of injury*, the resulting *damages* to the plaintiffs, and other factors to reach a verdict. Thus, potential causation, in the sense of hazard, adverse effect, and risk are necessary but not sufficient aspects of tort law cases. To prevail, plaintiffs must meet all of these aspects, and not just establish a strong causal set of scientific facts.

Toxic torts and tort law in general have been subjected to many attempts to reform their legal structure, in part because of the magnitude of punitive damages (awarded if the breach of duty is deemed to be beyond negligence on the part of the defendants). Although the magnitude of awards by juries (particularly in the United States) falls outside the scope of health risk assessment, it is relevant to risk management and should be considered in prudent risk management. The risk manager may use probabilistic simulations to include ranges of options and their overall consequences using, for example, decision analysis to account for varying amounts of

damages, contingent on the outcome from potential law suits (and include the cost of settlements or having to go to trial). Game-theoretic models of pre-trial arbitration and settlement [6] have also been extensively developed, and QRA methods and models can provide crucial information to those approaches by helping the parties potentially to agree on a settlement based on the quantitative probabilistic relation between defendant (and, perhaps, plaintiff actions) and resulting harm to the plaintiff, rather than proceeding to a trial that can be costly as well as result in an unpredictable outcome for the parties.

Toxicity (Adverse Events)

An adverse event (AE), or toxicity, in a clinical trial setting (*see* **Randomized Controlled Trials**), is any unfavorable change in structure (signs), function (symptoms), or chemistry (laboratory findings) in a subject or patient that is temporally associated with participation in the trial, whether or not this change is related to the trial intervention [1]. An AE is treatment emergent if it is not present prior to the start of the clinical trial, is not associated with a prior medical condition, and develops or worsens (if present at the start of the trial) during the trial [1]. Treatment-emergent AEs are classified on the basis of their relatedness to the therapeutic intervention: unrelated (clearly not related); unlikely related (doubtfully related); possibly related (may be related); probably related (likely related); or definitely related (clearly related) [2]. We note that, in randomized controlled trials, only increases in AEs in the intervention group compared with the control group are attributable to the intervention. An AE that is unrelated to the therapeutic intervention could be attributable to a concomitant medication (i.e., a medication prescribed for a coexisting disease).

A serious adverse event (SAE) is an AE that is at least possibly related to the intervention and that results in death; life-threatening experience; inpatient hospitalization or prolongation of existing hospitalization; persistent and significant disability or incapacity; jeopardy to patient and requires intervention; or a congenital anomaly or birth defect. Other important medical events may be considered SAEs if the patient or subject is jeopardized and requires medical or surgical intervention to prevent one of the outcomes of an SAE [2].

An unexpected adverse event is as any AE that is unanticipated in its nature or severity that may be related to the intervention [2].

In general, SAEs and unexpected AEs are reported to local Institutional Review Boards (IRBs), to study sponsors, and to appropriate regulatory authorities within 24 h [2].

We classify AEs using various standardized coding dictionaries. These dictionaries vary by regulatory group, study phase, disease, and type of therapy. For instance, the United States Federal Drug Administration (US FDA) used the Coding Symbols for Thesaurus of an Adverse Reaction Term (COSTART)

[3] until 1997; the FDA then instituted the use of the Medical Dictionary for Regulatory Activities (MedDRA [4]) developed by the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) [5]. The United States National Cancer Institute (US NCI) and the European Organization of Research and Treatment of Cancers (EORTC) use, for cancer studies, the Common Toxicity Criteria – version 2 (CTC v2.0 [6]) and the Common Terminology Criteria for Adverse Events – version 3 (CTCAE v3.0 [7]). Some research groups, for instance, the Radiation Therapy Oncology Group (RTOG) use the CTC v2.0 for acute (within 90 days from the start of therapy) and late (beyond 90 days from the start of therapy) radiation toxicities; others use the late effects on normal tissues (LENTs) scoring system and the subjective, objective, management and analytic (SOMA) scales for late radiation toxicities [8–10]. Studies run by the Eastern Cooperative Oncology Group (ECOG) use their own dictionary [11].

Most coding dictionaries classify AEs into five severity grades. For example, the grade definitions used in the CTC v2.0 [2] are as follows:

- 1 = mild adverse event
- 2 = moderate adverse event
- 3 = severe and undesirable adverse event
- 4 = life-threatening or disabling adverse event
- 5 = fatal adverse event.

Several coding dictionaries classify AEs in broad categories based on anatomy and/or pathophysiology (changes in body functionality caused by disease), and then classify them by a specific term within each category. In the CTCAE v3.0, for example, “autoimmune reaction” is a specific AE within the category of “allergy/immunology” [7].

In clinical trials, we perform routine laboratory tests before study enrollment or randomization (in controlled trials) to screen patients for eligibility and during the trials in order to ensure patient **Safety**. We consider a laboratory test result that is outside the normal range (as defined for a specific institution or group) as an abnormality. Such abnormal findings are unbiased indicators of changes in the chemistry of the body and are considered AEs.

Adverse experiences and serious adverse experiences are monitored throughout a clinical trial and are summarized to provide assessments of the **Safety** of the treatment under study.

Truncation

Types of Truncation

Truncation is one of the two major features that distinguish time-to-event data or failure-time data from other data and often occurs in risk analysis or other types of data [1]. The other feature is censoring [1, 2], which is discussed in a different article (see **Censoring**). Truncation represents or is usually defined as a condition in the study that produces the time-to-event data, and censoring usually refers to a type of incompleteness of observed data. For truncated data, only subjects who experience the events defining the condition and the times to the events of interest from those subjects are observed in the study. Subjects have to satisfy some conditions (e.g., exposure to a disease) or experience an intermediate event prior to the event of interest to be included in study. To give an example, suppose that one is interested in a follow-up study of subjects who were exposed to certain radiation to estimate their survival times after the exposure among other objectives. For this, one common design is to find and follow up on some subjects who were known to be exposed to the radiation. It is clear that a person who was exposed but died before the study was started would not be included in the study. For each subject in the study, his or her survival time T will be greater than the time Y , which is the period from the occurrence of the exposure to the radiation to the enrollment in the study. As defined below, this means that T is left truncated by Y .

Several types of truncations exist in practice: left truncation, right truncation, and general truncation. Let T denote the time to an event of interest, and let Y be the time to the truncation event. In left truncation, only subjects with $T \geq Y$ are observed or included in the study. A common example of left-truncated data is that subjects enter a study at a random time rather than at the origin of the event of interest, and are followed up from their delayed entry time to the occurrence of the event or to the time of being right censored. The reason behind this could be that subjects are simply not available for the study or study investigators. Another example of left truncation could be in a study of estimating cancer survival times based on a particular population. Some patients with cancer may not move

into the population and thus may not be included in the study until some time after the cancer is diagnosed. Also, subjects may have to experience a different intermediate event to be recognized as being at risk of experiencing the event of interest. In this case, the time to the occurrence of the intermediate event serves as the left-truncation time.

Another type of truncation that often occurs in risk and other studies is right truncation. Let T and Y be defined as before. In right truncation, only subjects with $T \leq Y$ are observed or included in the study. Right truncation occurs when only subjects who have experienced the event of interest are included in the study sample, and any subject who has not yet experienced the event is not observed. A common reason for this is the limitation of available information about the event or the study design. An example of right-truncated data arises from a mortality study based on death records. Of course, like censoring, a study could involve both left and right truncation [3].

Although there are many similarities between censoring and truncation, there are differences. One difference is that truncation often occurs with censoring but much less frequently. In consequence, there exists much less literature for the former than for the latter. Another difference between the two is that censored observations provide partial information about the response variable of interest, T , while the subjects who suffer truncation (or are truncated out) provide no information. To see this, consider again, the radiation example discussed above and suppose that the goal is to follow up and study a particular subpopulation who suffered certain radiation and for which the population size is unknown. Also suppose that the study started a while after the exposure occurred and there was no record of the subjects who had died from the exposure before the study commenced. In this case, as discussed above, the survival time of each subject in the study is left truncated and, in particular, it is unknown how many people were left out of the study owing to the left truncation caused by death. In contrast, if the study started right after the exposure, then one would not have to face the truncation and only censoring may exist. Specifically, the sample or subpopulation size is known.

The third type of truncation is general truncation, which occurs when, for example, one measures concentration of exposure to contamination (e.g.,

contaminated drinking water or radon exposure in homes [3, 4]). This is limited by the instrument's precision. When characterizing risk, risk factors are assumed to have some distribution (e.g., log normal distribution). Truncation makes the resulting distribution of the risk, which is assumed to be either a multiplicative or a general risk function, very complex. We discuss this issue in another articles (see **Risk Characterization and Uncertainty and Variability Characterization and Measures in Risk Assessment**). Here we focus on truncation in the context of time-to-event data.

Analysis of Truncated Data

As mentioned above, truncation often arises with censoring. Thus, most existing statistical approaches for truncated data were developed for both censored and truncated data. Let T and Y be defined as above, and assume that one observes right-censored and left-truncated data during the time to an event of interest. In this situation, the observed data have the form $\{X_i = \min(T_i, C_i), \delta_i = I(X_i = T_i), Y_i; i = 1, \dots, n\}$, where T_i and Y_i denote the same variables as defined above, but with subject i ; C_i denotes the right-censoring time associated with subject i , and δ_i is the censor indicator. Assume that both Y_i and C_i are independent of T_i as usual and all variables are continuous. Then the likelihood function can be written as

$$L = \prod_{i=1}^n \frac{f^{\delta_i}(x_i) [1 - F(x_i)]^{1-\delta_i}}{1 - F(y_i)} \quad (1)$$

where f and F denote the probability density function (pdf) and cumulative distribution function (cdf) of the T_i 's, respectively. The inference about F or any unknown parameters involved in F can be made on the basis of the maximum-likelihood approach.

It is interesting to note that if there is no truncation, that is, all $Y_i = 0$, the likelihood function L becomes

$$L = \prod_{i=1}^n f^{\delta_i}(x_i) [1 - F(x_i)]^{1-\delta_i} \quad (2)$$

On the other hand, without censoring, that is, all $C_i = \infty$, we have

$$L = \prod_{i=1}^n \frac{f(x_i)}{1 - F(y_i)} \quad (3)$$

since in this case, all $\delta_i = 1$. It is easy to see that, in terms of nonparametric estimation of F , the maximization of L in equation (2) gives an estimate of F over the whole support region, while the maximization of L in equation (3) only yields an estimate of F over $t \geq \max(y_i; i = 1, \dots, n)$.

In the case of right truncation or more general truncation with more general censoring, one can write the corresponding likelihood function similarly; this approach has been used by many authors. Among others, one of the early papers discussing truncation was given by Turnbull [3], who proposed a self-consistency algorithm for the nonparametric maximum-likelihood estimate of a distribution based on interval-censored [4] and truncated data. The algorithm applies to both right- and left-truncated data. More recently, Pan and Chappell [5] and Sun [6], among others, considered the one-sample estimation problem when left truncation and general truncation are involved. Lim *et al.* [7] also discussed the one-sample estimation problem with general truncation and the existence of a change point. For regression analysis of censored and truncated data, one can read Alioum and Commenges [8] and Pan and Chappell [9], who considered the problem by using the proportional hazards model [2].

Acknowledgment

This research was supported in part by the Grant CA21 765 from the National Institute of Health and by the American Lebanese Syrian Associated Charities (ALSAC). The authors thank Dr. Angela McArthur for the critical scientific editing. The authors are also grateful to the Editor and a referee for providing many helpful suggestions, which significantly improved the manuscript.

Ultrahigh Reliability

Ultrareliability is a broad approach to achieving high levels of system reliability by taking a system of systems perspective (*see Multistate Systems*). It involves analyzing each individual system component, interactions between the components, and the emergent effects when multiple components are combined. In the end, the objective is to increase reliability by a full order of magnitude compared to the traditional reliability process. It is best viewed as a process, with the benefits accruing continuously, as more of these interactions are addressed.

Table 1 lists the typical direct and indirect benefits of ultrareliability.

Types of Failures

In order to achieve these benefits, the scope of the analysis must include the physical failures on which reliability analysis often focuses, as well as behavioral and procedural failures. Behavioral failures are those caused by a human behavior that is on the root cause path of the failure. It could include failures caused by outright human negligent behavior, where behavior is the root cause, or it could be a training or communication failure that leads to an incorrect human behavior. Procedural failures are those that emerge when a process or procedure is inappropriate for a given situation, even when correctly applied. This can occur when system context changes without corresponding updates to the process or if the process was not developed correctly in the first place.

Analysis of Failures

As failures are identified, they are analyzed to understand the root cause, the path from the root cause to the failure, and the effects of the failure on the system. In general, there are six aspects of each failure that should be modeled: the root cause, the root cause path, contextual factors that increase or decrease the likelihood of failure, the overall probability of failure in each use context, the severity of the failure in each context, and possible methods to control or prevent the failure.

Stages of Reliability Evolution

As organizations begin to apply the concepts of ultrareliability to a system, they tend to evolve through a series of five stages. Pursuing this gradual approach tends to be more successful than attempting to jump directly to ultrareliability because many aspects of an ultrareliable system, such as management culture, take time to develop. The stages are as follows:

1. Reactive: failures are addressed and repaired as they occur.
2. Preventive: maintenance is conducted on a fixed schedule based on historical performance to prevent most failures.
3. Predictive: maintenance is conducted based on real-time data acquisition of system status to eliminate failures just in time.
4. Proactive: systems are tracked and modeled to understand why they fail and this insight is integrated into the design and specification processes.
5. Ultra: reliability is integrated at every stage of the system life cycle and interactions among system components are modeled.

System Life Cycle

The system life cycle can be divided into eight stages with three cycles of iteration (*see Figure 1*). While this chapter cannot go into significant details about every stage in detail, an overview can provide insight into how ultrareliability can be integrated into each stage.

Requirements Specification

Requirements specification is where the measures that define system success are determined (*see Subjective Expected Utility*). This should include reliability metrics as well as performance metrics. Key issues to achieve ultrareliability involve identifying the key stakeholders and the metrics that are critical to each one. Balanced scorecards [1] can be used to balance the needs of each group. Methods to solicit requirements are being adapted from diverse fields such as ethnography and marketing [2]. Integrating requirements analysis into early stages of the design process is critical to ensure that they are effectively supported. Iterative testing cycles can be used to verify and validate their delivery. Achieving ultrareliability also

Table 1 Typical direct and indirect benefits achieved through the application of ultrareliability to a system

Direct benefits	Reduced need for corrective and preventive maintenance, leading to lower maintenance costs and less disruption of normal operations
	Reduced inventory requirements for spare parts
	Reduced risk of catastrophic failure, with an associated reduction in safety risk for human operators and others in the proximity of the system when it fails
	Increased operating life of the system
Indirect benefits	Streamlined design and development process
	Fewer project delays and rework
	Better customer satisfaction and loyalty
	Greater return on investment
	Better understanding of why things fail

Figure 1 System life cycle for ultrareliability

requires that the landscape is continuously surveyed to track the evolution of stakeholder requirements and that these are integrated into the system even after it is launched.

Concept Development and Design

One of the key steps to maximize reliability is to use a systems perspective. This entails evaluating each component of the system, including architectural components, hardware, software, and user interface objects. Once the reliability of each component has been evaluated individually, the connections and modules are analyzed next. Then the full subsystems and the system as a whole are considered.

There are many modeling techniques that can be used individually or in combination to evaluate the reliability of components and subsystems. At the very least, a combination that considers both short-term and long-term failure profiles should be used. Adding safety factors, fault tolerances, and/or redundancy can increase the reliability of the system design. At a higher level, design strategies can pursue multiple concepts and test them against each other (see **Optimal Stopping and Dynamic Programming**).

Iterative Testing

Iterative cycles of testing are among the most effective strategies to maximize system effectiveness and reliability. As the design evolves and expands, additional cycles of testing should be executed. This can be accomplished cost-effectively and in a timely manner by using a variety of testing methods, such as simulation testing, low fidelity prototyping, and non-destructive testing. At later stages of the design process, integration testing and ecological field testing should be used. After the system has been launched, monitoring and reporting systems can be used to identify failures that were not predicted as well as validate the failure profiles that were not eliminated from the system design (see **R&D Planning and Risk Management**).

Operation, Maintenance, and Repair

After the system has been implemented, the next cycle should include operation, maintenance, and repair. While all design processes include these to some extent, there are techniques that can be

used to enhance reliability. At the operation stage, consideration should be given to the workflow, production schedules, workforce schedules, knowledge management, the use of automation, and housekeeping practices.

Workflows should be evaluated for their physical difficulty and cognitive complexity and how these are matched to the capabilities of the employee population. Production schedules should be reasonable, given the operational capabilities of machines and equipment. Workforce schedules should consider fatigue and error profiles of workers, given the challenges of vigilance [3] and fatigue [4]. Knowledge management requires a comprehensive strategy to facilitate participation [5]. Compliance and reliance-related system failures should be modeled for any automation that is used [6]. Finally, housekeeping practices should be evaluated for any possible links to degraded performance.

All systems require maintenance and repair operations at some point during their operation. These practices should be carefully designed to achieve the necessary system reliability. Maintenance and repair has a similar evolution to reliability in general. At the basic level, corrective maintenance involves using diagnostics to evaluate failures as they occur and repair them. Rapid intervention involves designing inspection practices to discover failures immediately as they occur to minimize the consequences of the failure. New developments in software, hardware, and material designs have created self-repairing systems that detect their own failures and take steps to repair them. The advanced phase of maintenance evolution is to take steps to prevent failures before they occur. This can be accomplished through preventive maintenance on fixed schedules based on historical failure rates, diagnostics that are monitored to identify states that may lead to failure for early intervention, and at the highest level, predictive modeling that predicts system failure based on individual system characteristics and context.

Incident Investigation

When unexpected/unplanned failures occur, a systematic incident investigation process is necessary to ensure that these failures are integrated into the operation/maintenance/repair cycle in the future. Note that this process is not about ‘accident’ investigation. The term accident connotes that the random aspect of the failure cannot be controlled. This

approach is unfortunate because an effective analysis can generally provide some control of every failure. Another common error in incident investigation is to attribute the failure to a proximate cause rather than continue the investigation until the root cause is identified and the root cause path is modeled.

There are two basic approaches to effective incident investigation. Root cause analysis involves combining theoretical and interview techniques to track the series of events that led to the failure. Stop rules are determined *a priori* to set a threshold for how far back to investigate.

The second approach is to establish an incident database that can be used to empirically analyze failures. As failures occur, the criteria and characteristics are stored in a database. The database is analyzed on a regular schedule to identify trends in failures and recurring contextual issues that contribute to failures.

Disposal

At the end of system life, either because of obsolescence or performance degradation, systems are disposed of. There are costs and consequences of this disposal that should be considered as part of the system design process. Some systems include hazardous wastes that can have environmental significance if not disposed of properly. Other systems may have warranties that can be managed to minimize the cost of replacement. Still other systems may have components that can be reused even as the rest of the system is scrapped. Typical strategies to plan for disposal include graceful degradation, obsolescence planning, end-of-life modeling, and disassembly planning. Environmental effects should also be modeled for all components and materials.

Interactions

One of the greatest challenges of ultrareliability is anticipating and modeling interactions among system components. The variability of failure profiles of each component are magnified when interactions are considered. There are several aspects of system performance that can be targeted to identify possible sources of failure that may be missed in a typical reliability analysis. These include management, training, communication, and human factors.

Management

Management is a common source of variability that can lead to system failure. At the broadest level, corporate cultures can develop that prioritize performance measures that are not aligned with customer demands. Similarly, supervisory and human resource practices can focus on unaligned measures. These can manifest in explicit organizational policies or in tacit practices that become accepted and permeate the organization.

Training

Even when system design and management practices are aligned, ineffective training can lead to system failure. Training design needs to consider the selection of media and content, the level of fidelity at which the training should be delivered, and the scheduling of training delivery. Employee performance in training and application must be measured and managed. Records must be maintained systematically, either through the use of certification or informally.

Communication

Ineffective communication is another contributor to system failure. As organizations become more geographically and culturally diverse, communication problems will be magnified [7]. The design and management of effective communication requires the consideration of communication mode, content, timing, tone, technology, and user characteristics. Modeling and controlling system failures requires consideration of the interactive effects of communication with design specifications.

Human Factors

Human factors involve describing the capabilities and limitations of all human components of the system and modeling on how they interact with system failure profiles. Categories of human capability include physical, motor, perceptual, cognitive, behavioral, and emotional. System requirements that exceed human capabilities clearly increase the likelihood and severity of failure. In addition, human capabilities change with context and these changes can also impact system failure profiles.

External Context

All systems are affected by their external context and this often has an impact on system reliability. For example, systems exist within an external culture depending on the region, the state of the economy, and the characteristics of internal and external customers. As globalization and international sourcing becomes more common, the ability of systems to succeed in a variety of societal cultures will increase in importance. The integration of value chains from basic resources through processing, manufacture, distribution, retail, delivery, and recently consumer participation creates new reliability challenges. Including these factors in the system design process and reliability analysis can enhance reliability significantly and reduce the impact or emergence of additional failures.

Case Study

On account of space limitations, this case study must be brief, but it will attempt to illustrate the contributions to ultrareliability of some of the key stages and interactions of the system life cycle and context. Consider the capacity expansion of an oil company in a remote region such as a deepwater ocean rig or a pipeline in Alaska or a desert. Clearly, this is an expensive endeavor, relying on efficient and effective processes, and maximizing reliability is critical. Recent examples such as BP [8] glaringly illustrate the importance of ultrareliability.

Ultrareliability in the System Life Cycle

The system life cycle shown in Figure 2 has many stages. An ultrareliability approach at each stage can impact the system's ultimate performance. At the user requirements stage, the wide variety of stakeholders for this kind of project must be balanced. Financial requirements must be met or the project should not be initiated in the first place. Design requirements must be specified to ensure that the system has the capacity to meet necessary flow rates and the durability to last as long as the expected lifetime. The requirements of the workforce stationed in a remote location must be considered to achieve the necessary productivity and reliability. Contextual requirements such as withstanding extreme weather conditions or accommodating the needs of local residents should be

Figure 2 System life cycle, interactions, and external context for ultrareliability

included. Environmental and political requirements may also be critical for the system's success. Ignoring any of these aspects will reduce the eventual reliability of the system.

At the testing stage, using an ultrareliability approach is evident. Naturalistic testing must be used to evaluate the system performance in the harsh climate. Failures in remote areas or environmentally sensitive regions can be extremely expensive. Accelerated life testing should be used because of the extended duration for which the system is intended to last.

Advanced maintenance approaches, such as predictive maintenance and self-healing materials, are critical because bringing in maintenance personnel to

remote areas on an emergency basis can be difficult and costly. Scheduled noninvasive fatigue testing and similar measures can be used to verify that prediction models accurately reflect the degradation of the system over time.

Disposal is also an essential consideration because of the environmentally sensitive nature of the location and the use of hazardous materials, but in addition to having the appropriate procedures in place, measures must be taken to ensure that workers comply with these procedures and do not take shortcuts [9].

Reinvention is a stage that is often discounted, but is very important for long-term projects such as this case. New technologies, governmental policies,

environmental requirements, or economic realities can significantly change the requirements of the system over time. Constant monitoring of the landscape allows the company to be proactive in making changes and preempting legal or public relations challenges.

Interactions

Many of the interactions illustrated in Figure 2 significantly impact this case, particularly because of the remote location. Communication may not be always possible, so detailed procedures must be balanced with worker empowerment, to prevent on-site personnel from modifying important processes but allowing them to react to changing conditions. Training thus becomes essential to ensure that they are qualified, capable, and motivated to implement this balanced implementation. Management must be seen as committed to this approach or workers will discount the necessary activities to execute effectively. Each of these factors interacts, complicating the design of the system context and requiring an ultrareliability approach at all levels.

External Context

Last, but not least, the external context must be considered. The supply chain is critical because of the variety of technologies that must be combined to make a large infrastructure project of this kind of work. Compatibility issues will be the key. Any suppliers of outsourcing services must be also reviewed to verify that their personnel policies are also compatible. When workers from contractors work on the same facility as internal employees, different safety rules, incentive plans, and other management initiatives can play havoc with their ability to work together. System reliability can suffer as a result.

Conclusions

In order to elevate system reliability to the highest level, each of these aspects must be analyzed at the individual level, subsystem level, and integrated level. This perspective is the only way to achieve the goals of the ultrareliability process, but achieving these levels of reliability is not easy or simple, either from design or management perspectives. Ultrareliability can be addressed in two ways, depending on the commitment of management and the resources

available. A systematic, quantitative process to minimize all failure modes throughout the system can be attempted at the earliest stages of system design. This requires significant up-front investment of time and resources. Alternatively, a continuous improvement process can be used to reduce exposure to failure modes over time. This requires continuous attention, consistency of management support, and ongoing resource allocation to the ultrareliability effort, but the gradual nature of this approach is often easier to achieve.

Uncertainty Analysis and Dependence Modeling

Wags and Bogsats^a

“...whether true or not [it] is at least probable; and he who tells nothing exceeding the bounds of probability has a right to demand that they should believe him who cannot contradict him”. Samuel Johnson, author of the first English dictionary, wrote this in 1735. He was referring to the Jesuit priest Jeronimo Lobos’ account of the unicorns he saw during his visit to Abyssinia in the seventeenth century [1, p. 200].

Johnson could have been the apologist for much of what passed as decision support in the period after World War II, when think tanks, forecasters, and expert judgment burst upon the scientific stage. Most salient in this genre is the book *The Year 2000* [2], in which the authors published 25 “even money bets” predicting features of the year 2000, including interplanetary engineering and conversion of humans to fluid breathers. Essentially, these are statements without pedigree or warrant, whose credibility rests on shifting the burden of proof. Their cavalier attitude toward uncertainty in quantitative decision support is representative of the period. Readers interested in knowing how many of these even money bets the authors have won, and in other examples from this period are referred to [3, Chapter 1].

Quantitative models pervade all aspects of decision making, for example, failure probabilities of unlaunched rockets, risks of nuclear reactors, effects of pollutants on health and the environment, or consequences of economic policies. Such quantitative models generally require values for parameters that cannot be measured or assessed with certainty. Engineers and scientists sometimes cover their modesty with churlish acronyms designating the source of ungrounded assessments. Wild-ass guess “(Wags)” and bunch of guys sitting around a table “(bogsats)” are two examples found in published documentation.

Decision makers, especially those in the public arena, increasingly recognize that input to quantitative models is uncertain, and demand that this uncertainty be quantified and propagated through the models (*see Decision Modeling*).

Initially, the modelers were the ones who provided assessments of uncertainty and did the propagating. Not surprisingly, this activity was considered secondary to the main activity of computing “nominal values” or “best estimates” to be used for forecasting and planning, and received cursory attention.

Figure 1 shows the result of such in-house uncertainty analysis performed by the National Radiological Protection Board (NRPB) and The Kernforschungszentrum Karlsruhe (KFK) in the late 1980s [4, 5]. The models in question predict the dispersion in the atmosphere of radioactive material following an accident with a nuclear reactor. The figure shows predicted lateral dispersion under stable conditions, and also shows wider and narrower plumes, which the modelers are 90% certain will enclose an actual plume under the stated conditions.

It soon became evident that if things were uncertain, then experts might disagree, and using one expert-modeler’s estimates of uncertainty might not be sufficient. Structured expert judgment (*see Expert Judgment*) has since become an accepted method for quantifying models with uncertain input. “Structured” means that the experts are identifiable, the assessments are traceable, and the computations are transparent. To appreciate the difference between structured and unstructured expert judgment, Figure 2 shows the results of a structured expert judgment quantification of the same uncertainty pictured in Figure 1 [6]. Evidently, the picture of uncertainty emerging from these two figures are quite different.

One of the reasons for the difference between these figures is the following: the lateral spread of a plume as a function of down wind distance x is modeled, per stability class, as

$$\sigma(x) = Ax^B \quad (1)$$

Both the constants A and B are uncertain, as attested by spreads in published values of these coefficients. However, these uncertainties can *not* be independent. Obviously, if A takes a large value, then B will tend to take smaller values. Recognizing the implausibility of assigning A and B as *independent* uncertainty distributions, and the difficulty of assessing a joint distribution on A and B , the modelers elected to consider B as a constant; that is, as known with certainty.^b

The differences between these two figures reflect a change in perception regarding the goal of quantitative modeling. With the first picture the main effort

Figure 1 Plume widths (stability D) of 5, 50, and 95% computed by NRPB and KFK

Figure 2 Plume widths (stability D) of 5, 50, and 95% computed by the EU-USNRC Uncertainty Analysis of accident consequence codes

has gone into constructing a quantitative deterministic model, to which uncertainty quantification and propagation are added on; however, in the second picture, the model is essentially about capturing uncertainty. Quantitative models are useful insofar as they help us resolve and reduce uncertainty. Three major differences in the practice of quantitative decision support follow from this shift in perception.

- First of all, the representation of uncertainty *via* expert judgment, or some other method is seen as a scientific activity subject to methodological rules every bit as rigorous as those governing the use of measurement or experimental data.
- Second, it is recognized that an essential part of uncertainty analysis is the analysis of dependence. Indeed, if all uncertainties are independent, then their propagation is mathematically trivial (though perhaps computationally challenging). Sampling and propagating independent

uncertainties can easily be trusted to the modelers themselves. However, when uncertainties are dependent, things become much more subtle, and we enter a domain for which modelers' training has not prepared them.

- Finally the domains of communication with the problem owner, model evaluation, etc. undergo significant transformations, once we recognize that the main purpose of models is to capture uncertainty.

Uncertainty Analysis and Decision Support: a Recent Example

A recent example serves to illustrate many of the issues that arise in quantifying uncertainty for decision support. The example concerns transport of *Campylobacter* infection in chicken processing lines.

The intention here is not to understand *Campylobacter* infection, but to introduce topics later in this entry. For details on *Campylobacter*, see [7–9].

Campylobacter contamination of chicken meat may be responsible for up to 40% of *Campylobacter* associated gastroenteritis and for a similar proportion of deaths. A recent effort to rank various control options for *Campylobacter* contamination has led to the development of a mathematical model of a processing line for chicken meat (these chickens are termed *broilers*).

A typical broiler processing line involves a number of phases as shown in Figure 3. Each phase is characterized by transfers of *Campylobacter* colony forming units from the chicken surface to the environment, from the environment back to the surface, from the feces to the surface (until evisceration), and the destruction of the colonies. The general model, applicable with variations in each processing phase, is shown in Figure 4.

Figure 3 Broiler chicken processing line

Figure 4 Transfer coefficients in a typical phase of a broiler chicken processing line

Given the number of campylobacter on and in the chickens at the inception of processing, and given the number initially in the environment, one can run the model with values for the transfer coefficients and compute the number of campylobacter colonies on the skin of a broiler and in the environment at the end of each phase. Ideally, we would like to have field measurements or experiments to determine values for the coefficients in Figure 4. Unfortunately, these are not feasible. Failing that, we must quantify the *uncertainty* in the transfer coefficients, and propagate this uncertainty through the model to obtain uncertainty distributions on the model output.

This model has been quantified in an expert judgment study involving 12 experts [9]. Methods for applying expert judgments are reviewed in [3, 10]. We may note here that expert uncertainty assessments are regarded as statistical hypotheses which may be tested against data and combined with a view to optimize performance of the resulting “decision maker”.

The experts have detailed knowledge of processing lines; but, owing to the scarcity of measurements, they have no direct knowledge of the transfer mechanisms defined by the model. Indeed, use of environmental transport models is rather new in this area, and unfamiliar. Uncertainty about the transfer mechanisms can be large; and, as in the dispersion example discussed above, it is unlikely that these uncertainties could be independent. Combining possible values for transfer and removal mechanism independently would not generally yield a plausible picture. Hence, uncertainty in one transfer mechanism cannot be addressed independently of the rest of the model.

Our quantification problem has the following features:

- There are no experiments or measurements for determining values.
- There is relevant expert knowledge, but it is not directly applicable.
- The uncertainties may be large and may not be presumed to be independent, and hence dependence must be quantified.

These obstacles will be readily recognized by anyone engaged in mathematical modeling for decision support beyond the perimeter of direct experimentation and measurement. As the need for quantitative decision support rapidly outstrips the resources of experimentation, these obstacles must be confronted and overcome. The alternative is regression to wages and bogsats.

Although experts cannot provide useful quantification for the transfer coefficients, they are able to quantify their uncertainty regarding the number of campylobacter colonies on a broiler in the situation described below taken from the elicitation protocol:

At the beginning of a new slaughtering day a thinned-flock is slaughtered in a 'typical large broiler chicken slaughterhouse'. ... We suppose every chicken to be externally infected with 10^5 campylobacters per carcass and internally with 10^8 campylobacters per gram of caecal content at the beginning of each slaughtering stage.... Question A1: All chickens of the particular flock are passing successively each slaughtering stage. How many campylobacters (per carcass) will be found after each of the mentioned stages of the slaughtering process, each time on the first chicken of the flock?

Experts respond to questions of this form, for different infection levels, by stating the 5, 50, and 95% quantiles, or percentiles of their uncertainty distributions. If distributions on the transfer coefficients in Figure 4 are given, then distributions, per processing phase, for the number of campylobacter per carcass (the quantity assessed by the experts) can be computed by Monte Carlo simulation: we sample a vector of values for the transfer coefficients, compute a vector of campylobacter per carcass, and repeat this until suitable distributions are constructed. We would like the distributions over the assessed quantities computed in this way to agree with the quantiles given by the combined expert assessments. Of course, we could guess an initial distribution over

the transfer coefficients, perform this Monte Carlo computation, and see if the resulting distributions over the assessed quantities happen to agree with the experts' assessments. In general, they will not, and this trial-and-error method is quite unlikely to produce agreement. Instead, we start with a diffuse distribution over the transfer coefficients, and adapt this distribution to fit the requirements in a procedure called *probabilistic inversion*.

More precisely, let X and Y be n - and m -dimensional random vectors, respectively, and let G be a function from $\mathbb{R}^n$ to $\mathbb{R}^m$. We call $x \in \mathbb{R}^n$ an inverse of $y \in \mathbb{R}^m$ under G if $G(x) = y$. Similarly, we call X a probabilistic inverse of Y under G if $G(X) \sim Y$, where $\sim$ means 'has the same distribution as'. If $\{Y|Y \in C\}$ is the set of random vectors satisfying constraints C , then we say that X is an element of the probabilistic inverse of $\{Y|Y \in C\}$ under G if $G(X) \in C$. Equivalently, and more conveniently, if the distribution of Y is partially specified, then we say that X is a probabilistic inverse of Y under G if $G(X)$ satisfies the partial specification of Y . In the current context, the transfer coefficients in Figure 4 play the role of X , and the assessed quantities play the role of Y .

In our campylobacter example, the probabilistic inversion problem may now be expressed as follows: find a joint distribution over the transfer coefficients, such that the quantiles of the assessed quantities agree with the experts' quantiles. If more than one such joint distribution exists, pick the least informative of these. If no such joint distribution exists, pick a "best fitting" distribution, and assess its goodness of fit.

In fact, the best fit produced with the model in Figure 4 was not very good. It was not possible to find a distribution over the transfer coefficients which, when pushed through the model, yielded distributions matching those of the experts. Reviewing the experts' reasoning, it was found that the "best" expert in fact recognized two types of transfer from the chicken skin to the environment. A rapid transfer applied to campylobacter on the feathers, and a slow transfer applied to campylobacter in the pores of the skin. When the model was extended to accommodate this feature, a satisfactory fit was found. The second model, developed after the first probabilistic inversion, is shown in Figure 5.

Distributions resulting from probabilistic inversion typically have dependencies. In fact, this is one of the

Figure 5 Processing phase model after probabilistic inversion

ways in which dependence arises in uncertainty analysis. We require tools for studying such dependencies. One simple method is simply to compute rank correlations. Rank correlation is the correlation of the quantile transforms of the random variables, where the quantile transform simply replaces the value of a random variable by its quantile. There are many reasons for preferring the rank correlation to the more familiar product moment correlation in uncertainty analysis.^c For now, it will suffice simply to display in Table 1 the rank correlation matrix for the transfer coefficients in Figure 5, for the scalding phase.

Table 1 shows a pronounced negative correlation between the rapid transfer from the skin (a_{extA}) and evacuation from the chicken (ca), but other correlations are rather small. Correlations do not tell the whole story; they are averages after all. To obtain a detailed picture of interactions, other tools must be applied. One such tool is the cobweb plot. In a cobweb plot, variables are represented as vertical lines. Each sample realizes one value

of each variable. Connecting these values by line segments, one sample is represented as a jagged line intersecting all the vertical lines. Figure 6 shows 2000 such jagged lines and gives a picture of the joint distribution. In this case we have plotted the quantiles, or percentiles, or ranks of the variables rather than the values themselves. Contracting the name of a_{extA} to axa , the negative rank correlation between axa and ca is readily visible if the picture is viewed in color: the lines hitting low values of a_{extA} are red, and the lines hitting high values of ca are also red.

We see that the rank dependence structure is quite complex. Thus, we see that low values of the variable ce (c_{env} , the names have been shortened for this graph) are strongly associated with high values of b , but high values of ce may occur equally with high and low values of b . Correlation (rank or otherwise) is an average association over all sample values and may not reveal complex interactions that are critical for decision making. One simple illustration highlights their use in this example.

Suppose we have a choice of accelerating the removal from the environment ce or from the chicken ca ; which would be more effective in reducing campylobacter transmission? To answer this, we add two output variables: $a1$ (corresponding to the elicitation question given above) is the amount on the *first* chicken of the flock as it leaves the processing phase, and $a2$ is the amount on the *last* chicken of the flock as it leaves the processing phase. In Figure 7, we have conditionalized the joint distribution by

Table 1 Rank correlation matrix of transfer coefficients, scalding phase

Variable	a_{extA}	a_{extB}	ca	b	ce	$aint$
a_{extA}	1.00	0.17	-0.60	-0.04	0.03	0.00
a_{extB}	0.17	1.00	-0.19	-0.10	-0.06	0.00
ca	-0.60	-0.19	1.00	0.01	0.02	0.00
b	-0.04	-0.10	0.01	1.00	0.02	0.00
ce	0.03	-0.06	0.02	0.02	1.00	0.00
$aint$	0.00	0.00	0.00	0.00	0.00	0.00

Figure 6 Cobweb plot for the transfer coefficients in the extended model

Figure 7 Cobweb plot conditional on high *ca*

Figure 8 Cobweb plot conditional on high *ce*

selecting the upper 5% of the distribution for *ca*; in Figure 8, we do the same for *ce*.

Let us assume that the intervention simply conditionalizes our uncertainty, without changing other causal relations in the processing line (otherwise, we should have to rebuild our model). On this assumption, it is readily apparent that *ce* is more effective than that on *ca*, especially for the last chicken.

This example illustrates a feature that pervades quantitative decision support, namely, that input parameters of the mathematical models cannot be known with certainty. In such situations, mathematical models should be used to capture and propagate uncertainty. They should not be used to help a bunch of guys sitting around a table make statements that should be believed if they cannot be contradicted. In particular, it shows that

- Expert knowledge can be brought to bear in situations where direct experiment or measurement is not possible, namely, by quantifying expert uncertainty on variables that the models should predict.
- Utilizing techniques like probabilistic inversion in such situations, models become vehicles for capturing and propagating uncertainty.

- Configured in this way, expert input can play an effective role in evaluating and improving models.
- Models quantified with uncertainty, rather than wags and bogsats, can provide meaningful decision support.

Uncertainty Analysis – the State of the Art

The following remarks focus on techniques for uncertainty analysis that are generally applicable. This means, uncertainty distributions may *not* be assumed to conform to any parametric form and techniques for specifying, sampling, and analyzing high dimensional distributions should therefore be nonparametric.

Some techniques, in particular, those associated with bivariate dependence modeling, are becoming familiar to a wide range of users. Copulae, or multivariate distributions with uniform margins are used to capture rank correlation structure which is independent of marginal distributions (*see Copulas and Other Measures of Dependency*). While two-dimensional copulae are becoming familiar, multidimensional copulae remain extremely limited in their ability to represent dependence. Good books are available for bivariate dependence, such as [11–14].

High dimensional dependence models, sampling methods, postprocessing analysis, and probabilistic inversion are “breaking news” to nonspecialists, both mathematicians and modelers.

With regard to dependence in higher dimensions, much is not known. For example, we do not know whether an arbitrary correlation matrix is also a rank correlation matrix.^d We do know that characterizing dependence in higher dimensions *via* product moment correlation matrices is *not* the way to go. Product moment correlations impose unwelcome constraints on the one-dimensional distributions. Further, correlation matrices must be positive definite, and must be completely specified. In practice, data errors, rounding errors, or simply vacant cells lead to intractable problems with regard to positive definiteness. We must design other, friendlier ways to let the world tell us, and to let us tell computers which high dimensional distribution to calculate. We take the position that graphical models are the weapon of choice. These may be Markov trees, vines, independence graphs or Bayesian belief nets. For constructing sampling routines capable of realizing richly complex dependence structures, we advocate regular vines. They also allow us to move beyond discrete Bayesian belief nets without defaulting to the joint normal distribution. Much of this material is new and only very recently available in the literature [15–20].

Problems in measuring, inferring, and modeling high dimensional dependencies are mirrored at the end of the analysis by problems in communicating this information to problem owners and decision makers. This is sometimes called *sensitivity analysis* [21].

Whereas, communicating uncertainty has received some attention, much less attention has gone into *utilizing* uncertainty. It is safe to say that our ability to quantify and propagate uncertainty far outstrips our ability to *use* this quantification to our advantage in structured decision problems.

End notes

^a. This chapter is based on the first Chapter of [1] to which the reader may refer for definitions and details.

^b. This is certainly not the only reason for the differences between Figures 1 and 2. There was also ambivalence with regard to what the uncertainty should capture. Should it capture the plume uncertainty in a single accidental release, or the

uncertainty in the average plume spread in a large number of accidents? Risk analysts clearly required the former, but meteorologists are more inclined to think in terms of the latter.

^c. Among them the rank correlation always exists, is independent of the marginal distributions, and is invariant under monotonic increasing transformations of the original variables.

^d. We have recently received a manuscript from H. Joe that purports to answer this question in the negative for dimension greater than four.

Uncertainty and Variability Characterization and Measures in Risk Assessment

The risks experienced by individuals within a given population can vary appreciably owing to differences in susceptibility and exposure patterns [1]. Susceptibility can vary depending on genetic predisposition to certain diseases such as cancer or pharmacokinetic factors that control the rates of metabolism and elimination of xenobiotics from the body. Susceptibility can also vary as a function of age, e.g., developing tissues in the pediatric population are sometimes more susceptible than adult tissues. Exposure to environmental toxicants can markedly vary among individuals; food consumption patterns influencing dietary intake of naturally occurring or synthetic dietary components vary both among individuals and within an individual over time (*see Managing Foodborne Risk; Environmental Hazard*).

In the past, conservative assumptions have often been invoked in the face of uncertainty and variability. In the absence of evidence to the contrary, it is often assumed that humans are as sensitive as the most sensitive animal species tested. When exposure varies greatly, consideration is given to the risks faced by individuals at or toward the upper end of the exposure range. These conservative assumptions can compound and lead to much higher estimates of risk than warranted [2]. Although such conservative strategies are appropriate in the interests of public health protection, excessive conservatism can be cost ineffective. Moreover, by focusing on single-summary estimates of risk obtained by the application of conservative inference guidelines, one can lose sight of the fact that such estimates are more properly viewed as upper limits rather than as best estimates.

Distinguishing clearly between uncertainty and variability is very important in quantitative risk assessment [3–5]. Uncertainty represents the degree of ignorance about the precise value of a particular parameter (risk factor) such as the body weight of a given individual. In this case, uncertainty may be

caused by a systematic or random error associated with the instrument (e.g., a simple scale or more sophisticated mass balance) used to measure that parameter. Variability represents inherent variation in the value within the population of interest. In addition to being uncertain, body weight also varies among individuals. A parameter such as body weight, which can be determined with a high degree of accuracy and precision and may be subject to little uncertainty, can be highly variable. Other parameters may be subject to little variability but substantial uncertainty, or they may be both highly uncertain and highly variable.

For the purposes of this article, uncertainty and variability are defined as follows. When the input variable is fixed (deterministic in a broad sense) but unknown, the distribution of values obtained from repeated observations represents uncertainty. The repeated observations can be used to construct a confidence interval for which there is a given percent chance of bounding the true value. Note that large amounts of uncertainty indicate that the information base for decision making may be improved by additional research in areas where information is most doubtful. When the input variable is stochastic and represented by a distribution with known parameters, variability is present in the input variable. Note that, other things being equal, large amounts of real variability indicate that societal resources may be more efficiently targeted to reduce risk where it is most intense. An input variable can have both uncertainty and variability. When the input variable is stochastic and represented by a distribution with unknown parameters, variability is present in the input variable, and uncertainty is present in the parameters of the distribution of the input variable.

In the remainder of this article, we consider a general framework for the analysis of uncertainties in a general risk model in which the input variables are stochastic. In the section titled “General Risk Model Incorporating Uncertainty and Variability”, we describe a general risk model in which the input variables are subject to uncertainty, variability, or both. The section also describes a graphical as well as numerical measure of uncertainties. In the section titled “Discussion”, we present the discussion on uncertainty and variability in a general risk model. The article concludes with some observations about

the assumptions that underlie the various measures that we have proposed.

General Risk Model Incorporating Uncertainty and Variability

In this section, we describe briefly a general risk model that incorporates uncertainty and variability in risk factors. Rai *et al.* [6] have developed a general framework for characterizing and analyzing uncertainty and variability for arbitrary risk models. Suppose that the risk R depends on p risk factors $X_1, \dots, X_p$ according to the function

$$R = H(X_1, X_2, \dots, X_p) \quad (1)$$

Each risk factor X_i may vary within the population of interest according to some distribution with probability density function $f_i(X_i|\theta_i)$, which is conditional upon the parameter θ_i . Uncertainty in X_i is characterized by the distribution $g_i(\theta_i|\theta_i^0)$ for θ_i , where θ_i^0 is a known constant. The total uncertainty/variability in X_i (marginal distribution of X_i) is then described by the density function

$$c_i(X_i|\theta_i^0) = \int f_i(X_i|\theta_i) g_i(\theta_i|\theta_i^0) d\theta_i \quad (2)$$

If θ_i is a vector valued, g_i is a multivariate distribution. Here, it is assumed that the forms of the distributions f and g are known.

For any correlated pair (i, j) , let X_i and X_j have a joint distribution f_{ij} , conditional upon the parameter θ_{ij} ; here, f_{ij} represents the joint distribution of variability in X_i and X_j . The parameter vector θ_{ij} , in turn, has a (possibly multivariate) distribution g_{ij} with known parameter θ_{ij}^0 ; here, g_{ij} represents the joint distribution of uncertainty in X_i and X_j . As described

below, the first two moments of these bivariate distributions can be used to describe uncertainty and variability in risk and characterization of risk.

Relative Uncertainty/Variability

Rai *et al.* [6] define uncertainty and variability measures in a Taylor series expansion of equation (1) around the means of the risk factors. However, in the risk models, many risk factors are assumed to be lognormally distributed. Also many risk models are multiplicative [7]. Therefore, developing uncertainty measures and distributions of the risk based on $R^* = \log R$ may be robust and appropriate.

For any $i, i = 1, 2, \dots, p$, let $X_i^* = \log X_i$ and $R^* = \log R$. For uncertainty analysis, we need only two moments, mean and variance (or standard deviation). We describe the tree diagram in Figures 1 and 2 to identify the terms needed for the uncertainty analysis.

Note that

$$E(X_i^*) = E_{g_i} E_{f_i}(X_i^*) = E_{g_i}(m_i) = \mu_i^0 \quad (3)$$

Figure 1 Summary of uncertainty and variability in a risk factor. The factors that have $\sigma_i = 0$ are subject to only uncertainty and not variability, and those that have $\sigma_i^0 = 0$ and $\xi_i^0 = 0$ are subject to only variability and not uncertainty

Figure 2 Correlation between a pair of risk factors. The correlated factors that have $\tau_{ij}^0 = 0$ are subject to only variability but not uncertainty

$$\begin{aligned}\text{Var}(X_i^*) &= \text{Var}_{g_i}(m_i) + E_{g_i}(\sigma_i^2) \\ &= \sigma_i^{0^2} + (\eta_i^{0^2} + \xi_i^{0^2})\end{aligned}\quad (4)$$

and

$$\begin{aligned}\text{Cov}(X_i^*, X_j^*) &= \text{Cov}(m_i, m_j) + E(\sigma_{ij}) \\ &\cong \tau_{ij}^0 \sigma_i^0 \sigma_j^0 + \tau_{ij}^0 \eta_i^0 \eta_j^0\end{aligned}\quad (5)$$

By expanding the risk R^* , i.e., risk measured on a logarithmic scale, around the point $(X_1^* = \mu_1^0, X_2^* = \mu_2^0, \dots, X_p^* = \mu_p^0)$ by using Taylor series expansion and ignoring all but the first-order terms, we have

$$\begin{aligned}R^* &\approx \tilde{R}^* = \log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0) \\ &\quad + \sum_{i=1}^p h_i (X_i^* - \mu_i^0)\end{aligned}\quad (6)$$

where

$$\begin{aligned}h_i &= \frac{\mu_i}{H(\mu_1, \dots, \mu_p)} \\ &\times \left. \frac{\partial H(X_1, X_2, \dots, X_p)}{\partial X_i} \right|_{(\mu_1^0, \mu_2^0, \dots, \mu_p^0)}\end{aligned}\quad (7)$$

is the partial derivative of H with respect to X_i . This approximation reduces the log-scale risk R^* to a simple linear combination of the p risk factors measured on the log scale X_i^* . When the risk factor is multiplicative, $h_i = 1$. Rai and Krewski [8] defined uncertainty measures for the multiplicative model.

Partitioning Uncertainty (U) and Variability (V)

Following Rai *et al.* [6] and Rai and Krewski [8], we now derive an expression for U , which is the measure of uncertainty in R due to uncertainty in all of the risk factors combined, and V , which is the measure of variability in R that encompasses the variability in all of the risk factors. Without loss of generality, we can assume that the variables $X_1, \dots, X_{p_1}$ in equation (2) are subject only to uncertainty, that $X_{p_1+1}, \dots, X_{p_1+p_2}$ exhibit only variability, and that the remaining $p - (p_1 + p_2)$ variables are subject to both variability and uncertainty. Thus,

$$\begin{aligned}\tilde{R}^* &= \log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0) + \sum_{i=1}^{p_1} h_i (X_i^* - \mu_i^0) \\ &\quad + \sum_{i=p_1+1}^{p_1+p_2} h_i (X_i^* - \mu_i^0) + \sum_{i=p_1+p_2+1}^p h_i (X_i^* - \mu_i^0)\end{aligned}\quad (8)$$

Following Rai and Krewski [8], we note that equation (8) leads to

$$\begin{aligned}U &= \sum_{i=1}^{p_1} h_i^2 \text{Var}(X_i^*) + \sum_{p_1+p_2+1}^p h_i^2 \text{Var}(m_i) \\ &\quad + \sum_{i=1}^{p_1} \sum_{j(\neq i)=1}^{p_1} h_i h_j \text{Cov}(m_i, m_j) = \sum_{i=1}^{p_1} h_i^2 \sigma_i^{0^2} \\ &\quad + \sum_{p_1+p_2+1}^p h_i^2 \sigma_i^{0^2} + \sum_{i=1}^{p_1} \sum_{j(\neq i)=1}^{p_1} h_i h_j \rho_{ij}^0 \sigma_i^0 \sigma_j^0\end{aligned}\quad (9)$$

and

$$\begin{aligned}V &= \sum_{i=p_1+1}^{p_1+p_2} h_i^2 \text{Var}(X_i^*) + \sum_{p_1+p_2+1}^p h_i^2 E(\sigma_i^2) \\ &\quad + \sum_{i=1}^{p_1} \sum_{j(\neq i)=1}^{p_1} h_i h_j E(\sigma_{ij}) = \sum_{i=p_1+1}^{p_1+p_2} h_i^2 \eta_i^{0^2} \\ &\quad + \sum_{p_1+p_2+1}^p h_i^2 (\eta_i^{0^2} + \xi_i^{0^2}) + \sum_{i=1}^{p_1} \sum_{j(\neq i)=1}^{p_1} h_i h_j \rho_{ij}^0 \eta_i^0 \eta_j^0\end{aligned}\quad (10)$$

The total uncertainty/variability in R due to all factors is given as

$$W = U + V\quad (11)$$

The total uncertainty/variability in R due to X_i is given as

$$W_i = U_i + V_i\quad (12)$$

where

$$\begin{aligned}U_i &= h_i^2 \text{Var}(m_i) + \sum_{j(\neq i)=1}^p h_i h_j \text{Cov}(m_i, m_j) \text{ and} \\ V_i &= h_i^2 E(\sigma_i^2) + \sum_{j(\neq i)=1}^p h_i h_j E(\sigma_{ij})\end{aligned}\quad (13)$$

Note that when the risk factors $X_1, \dots, X_p$ are independent, the covariance terms vanish. In this case, the evaluation of individual uncertainty and variability may be easy. Also note that some other alternatives for uncertainty and variability in a correlated risk factor defined in equation (13) are possible. These partitioned variances can be used to find the influential risk factors, contributions to risk made by uncertainty, variability, or both.

Following Rai *et al.* [9], these measures of uncertainty and variability are used to define

useful relative indicators showing the percentage of uncertainty and/or variability due to different sources. Specifically, the percentage of overall uncertainty and variability W in R due to uncertainty and variability W_i in X_i is denoted by $RW_i = (W_i/W) \times 100$. Similarly, $RU = (U/W) \times 100$ and $RV = (V/W) \times 100$ indicate the percentages of overall uncertainty and variability due to uncertainty U and variability V , respectively. Also, $RU_i = (U_i/W) \times 100$ and $RV_i = (V_i/W) \times 100$ are the percentages of overall uncertainty and variability W due to uncertainty U_i due to X_i and variability V_i in X_i , respectively.

Furthermore, $RU_i^{(a)}$ and $RV_i^{(a)}$ denote the percentages of uncertainty and variability W_i in X_i due to uncertainty U_i in X_i and variability V_i in X_i , respectively. The measures $RU_i^{(b)}$ and $RV_i^{(b)}$ denote the percentage of overall uncertainty U due to uncertainty U_i in X_i and the percentage of overall variability V due to variability V_i in X_i , respectively.

Risk Distributions

To provide the fullest possible characterization of risk, consider the distribution of R^* . Allowing for both uncertainty and variability in risk, the distribution of R^* is given by

$$C^*(R^* \leq r^*) = \int_{\log H(x_1, \dots, x_p) \leq r^*} \times \int c(X_1, \dots, X_p | \theta^0) dX_p, \dots, dX_1 \quad (14)$$

where $c(\cdot)$ is a joint-density function of all the risk factors. The parameter of this joint distribution is $\theta^0 = \{\theta_i^0, \theta_{ij}^0; i, j = 1, \dots, p\}$. The joint-density function, $c(\cdot | \theta^0)$, can be partitioned into two parts: $f(\cdot | \theta)$ represents the joint density due to the variability in the risk factors and $g(\cdot | \theta^0)$ represents the joint-density function due to uncertainty in the risk factors. The probability function (11) can then be further expanded as follows:

$$C^*(R^* \leq r^*) = \int_{\log H(x_1, \dots, x_p) \leq r^*} \times \int \{f(X_1, \dots, X_p | \theta) dX_p, \dots, dX_1\} \times \{g(\theta | \theta^0) d\theta\} \quad (15)$$

The mean and variance of the distribution of R^* can be approximated by $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and W .

If all of the risk factors in equation (1) are lognormally distributed and the risk model is of the multiplicative form, then the distribution of R^* is normal with a mean $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and variance W . Risk factors are typically assumed to be beta, triangular, or log-triangular distributed, if not lognormally distributed. In this case, they can be approximated very well by a lognormal distribution. Thus, if all of the risk factors are approximately lognormally distributed, then the distribution of R^* can be approximated by a normal distribution. The distribution of R^* can also be approximated by Monte Carlo simulation. Although straightforward, Monte Carlo simulation can become computationally intensive with a moderate number of risk factors.

In addition to examining the distribution of R^* and taking into account both uncertainty and variability in the $\{X_i\}$, it is of interest to examine the distribution of R^* considering only uncertainty in the $\{X_i\}$ or only the variability in the $\{X_i\}$. By comparing the distributions of R^* and allowing uncertainty and variability, only variability, or only uncertainty, one can gauge the relative contribution of uncertainty and variability to the overall uncertainty/variability in risk.

The density of R^* based on only uncertainty in the $\{X_i\}$ is the density of $\log H(X_1, X_2, \dots, X_p)$, but the risk factors $\{X_i^*\}$ are replaced by m_i , where

$$m_i = E_{f_i}(X_i^*) = \int_{-\infty}^{\infty} X_i^* f_i(X_i | \theta_i) dX_i \quad (16)$$

Note that this density depends on the distribution of the means of the log-scaled risk factors. For example, if the risk factor X_i has a lognormal distribution, then equation (16) reduces to a simple expression. Under some mild restrictions, this density can be approximated by a normal distribution with a mean $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and variance U .

The density of R^* based on only variability in the $\{X_i\}$ is the density involving $\{\tilde{X}_i^*\}$ in the general risk model, where $\tilde{X}_i^*$ has distribution f_i with the following known parameter:

$$E_{g_i}(\theta_i) = \int_{-\infty}^{\infty} \theta_i g_i(\theta_i | \theta_i^0) d\theta_i \quad (17)$$

This density can also be approximated by a normal distribution with mean $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and variance U .

The density of R^* based on both variability and uncertainty, only uncertainty, or only variability in the risk factor X_i can be approximated by a normal distribution with a common mean $\log H(\mu_1^0, \mu_2^0, \dots, \mu_p^0)$ and variances W_i , U_i , and V_i , respectively.

Risk due to Exposure to Trihalomethanes in Drinking Water

For demonstration purposes, we briefly describe the example discussed in Rai *et al.* [9]. Trihalomethanes (THMs) form in drinking water, primarily as the result of chlorination of organic matter that is naturally present in untreated water supplies. THMs are classified as probably carcinogenic in humans. Although the available epidemiological evidence was considered incomplete, preliminary data were consistent with the hypothesis that chlorinated water, if not THMs, is causally related to human bladder and colon cancer [10]. Using the model given in Krewski *et al.* [11], we can calculate the cancer risk as 1.69×10^{-3} for a lifetime exposure to 1 mg/kg-body weight/day of chloroform. This is comparable to the unit risk of THMs given in the US Environmental Protection Agency's Integrated Risks Information System [12].

We can apply our probabilistic risk assessment techniques to evaluate the potential risk associated with the interim maximum acceptable concentration

(IMAC) of THMs. The risk R is computed as follows:

$$R = \frac{UR \times IMAC \times C}{BW \times 10^3} = 3.6 \times 10^{-6} \quad (18)$$

Here, UR denotes the unit risk associated with lifetime exposure to 1 mg/kg-body weight/day (1.69×10^{-3}) with the $IMAC$ set at $100 \mu\text{g l}^{-1}$. The factor BW denotes the average body weight of an adult (70 kg), and C is the average daily consumption of drinking water for an adult (1.51 day^{-1}). Descriptions of the uncertainty and variability distributions are given in Table 1.

The results of uncertainty and variability analyses are given in Table 2. The uncertainty in the unit risk estimate contributes 67.8% to the overall uncertainty and variability; thus, it is the most influential factor. Of the remaining factors, the rate of consumption of drinking water (86.1%) exhibits substantially more variability than does body weight (13.9%).

The distributions of uncertainty, variability, and both uncertainty and variability are displayed in Figure 3. The distributions of R due to uncertainty in all of the input variables, due to variability in all of the input variables, and due to both uncertainty and variability in all of the input variables are lognormal with the same geometric mean (0.75×10^{-6}) but with different geometric standard deviations (1.21, 1.50, and 1.82, respectively). Considering both uncertainty and variability (for a random individual) in the input variables, the lifetime risk is about 3.6×10^{-6} for more than 90% of the population. Thus, about 10%

Table 1 Distributions of uncertainty and variability in the probabilistic risk assessment of chloroform

of the population experiences higher risk than that set by the agency. To lower this percentage, the agency may want to adjust the *IMAC* level for this chemical.

Discussion

In this article, we have summarized a framework for addressing uncertainty and variability in a general

risk model for quantitative risk assessment. We have demonstrated an example of potential risks associated with the presence of THMs in drinking water. This method takes into account uncertainty and variability in each of the risk factors or input variables affecting risk to determine the overall uncertainty and/or variability in risk. Our methods also facilitate the identification of those factors that contribute the most to uncertainty and variability in risk. The objective of the example was not to revisit the established guidelines for acceptable THM levels in drinking water, but rather to illustrate how probabilistic risk assessment can provide a more complete characterization of risk than traditional best estimates or confidence limits of risk.

Note that our measures of uncertainty under a general (multiplicative or nonmultiplicative) model for risk utilize the full characterization of joint distribution of risk factors. Our measures take into account the resulting correlation structure due to any two risk factors.

One may fear that these results convey a false sense of reality about the nature of the data. However, on the contrary, we believe that such methodology helps to put the existing data in better context that could be used to better communicate the role of variability and uncertainty in determining risk and exposures.

Understanding Large-Scale Structure in Massive Data Sets

Massive data sets are ubiquitous in this day and age. New computer technologies have made and will continue to make data collection ever easier. At the same time increasing computer capabilities also enable development of new data analysis methods, but to what extent have the latter been brought to bear on the former? Or, do we require new thinking altogether to meet this challenge? (In this article we distinguish between massive data sets and massive data streams on the basis of whether or not they are stored. Massive data sets are recorded and available for follow-up analysis, while data streams are not. Analysis of massive data streams permit just one look at each datum as the stream flows.)

In 1995 the National Academy of Sciences Committee on Applied and Theoretical Statistics held a workshop on massive data sets. It included more than 50 participants from academia, industry, and government, who spoke about the nature of and challenges posed by massive data sets in such diverse areas as Earth and space science, information retrieval, social science, medicine, biology, business, manufacturing, telecommunications, high-energy physics, astronomy, text mining, national security, and government statistics [1]. At that time massive data sets were measured in gigabytes. Today they are measured in petabytes, and in the future they will no doubt be measured in exabytes and beyond. Nonetheless, many of the ideas presented at the workshop have borne fruit over the last decade. For example, there was extensive discussion at the workshop on the role of models in analyzing massive data sets. Later in this article we discuss the use of “local” models in understanding global structure.

We proceed as follows. First, we discuss various definitions of massive data sets. Then we review several analysis approaches that specifically make use of massiveness rather than simply scaling up existing techniques. This is followed by a discussion of how these methods can be used to understand the structure of massive data sets, and finally by a discussion of the challenges posed by massive data sets for understanding and managing risk.

What Are Massive Data Sets?

There are many ways to answer this question. Some have defined massive data sets on the basis of their sizes in bytes. For example, The Huber–Wegman taxonomy of massive data sets [2] is often cited, but now somewhat out of date in its absolute numbers. Others have concentrated on the idea of complexity both in information-theoretic and less formal senses [3]. In fact Wegman relates data set sizes to their computational, algorithmic, storage, transmission, and even visualization complexities [2], recognizing that it is difficult to give meaning to the idea of massiveness without some notion of how the data will be used.

Going even further, one can argue that massiveness depends not only on usage, but also on available resources: massiveness is in the eye of the beholder. An analyst with only a modest desktop computer may find a multiterabyte data set to be “massive” given his or her objectives while the same data set would not be considered massive by an analyst with access to a supercomputer.

A massive data set could be defined as one too large to be held in the memory of the user’s computer. This definition is criticized as overly broad, so instead we propose the following: a massive data set is a sample that is so large it can’t be analyzed like a sample. An analyst faced with such a data set might naturally choose to take and analyze a subsample from it, but this begs the question “what good are the original data if they are never used”?

Massive data sets occupy a middle-ground between populations and samples. They are like populations in the sense that making statements about them requires inference and sampling. They are like samples because they are collections of observations from even larger finite or infinite populations. If an analyst samples from and makes inferences about a massive data set, those inferences can be the basis for a second stage of inference back to the true population.

Figures 1 and 2 contrast the familiar statistical paradigm with a modified version that accommodates the role of massive data sets. Figure 1 shows schematically how a sample drawn from a population with distribution F , depending on unknown parameter(s) θ , is used to make inferences about θ . One computes a point estimate based on the sample, and it is the

Figure 1 The familiar statistical paradigm. The population is assumed to follow distribution F , which depends on parameter(s) θ . Interest is in estimating θ . A single sample is drawn from F , and the statistic $\hat{\theta}$ is computed. The sampling distribution of $\hat{\theta}$ is derived either mathematically or by simulation, and in either case represents the distribution of $\hat{\theta}$ that would be obtained by drawing many samples and computing $\hat{\theta}$ for each one. The position of $\hat{\theta}$ in the sampling distribution determines a confidence interval for θ

Figure 2 The statistical paradigm modified to incorporate the role of massive data sets

sampling distribution of that estimate, $\hat{\theta}$, that determines its uncertainty. The sampling distribution is represented in Figure 1 by the notion of other potential samples (designated by dashed lines) that may have been realized, and the values of $\hat{\theta}$ that would have been calculated from them.

In Figure 2, we depict our massive data set, $\tilde{F}_0$, as both a sample from the true population, F , and the data source for a subsequent sampling step. The latter is required because even though $\tilde{F}_0$ is itself a sample, it is too large to be treated like one according to our definition above. Just as there are unrealized potential samples that could have been drawn from F in Figure 1, there are unrealized potential massive data sets and unrealized potential samples from each of those in Figure 2.

To be more concrete, suppose as in Figure 1 that F is the underlying population distribution function, and that it depends on population parameter θ , e.g., the quantiles of F . F may be discrete or continuous. The massive data set collected by sampling from F is denoted by $\tilde{F}_0$, and is by definition a discrete, empirical distribution function. It depends on parameter $\tilde{\theta}_0$, which would be the quantiles of $\tilde{F}_0$ in this example. $\tilde{\theta}_0$ is unknown, and since $\tilde{F}_0$ is massive, it is not possible to calculate $\tilde{\theta}_0$ directly owing to the data set's size. Other massive data sets besides $\tilde{F}_0$ that could have been realized are represented by $\tilde{F}_1, \dots, \tilde{F}_L$, and their parameters by $\tilde{\theta}_1, \dots, \tilde{\theta}_L$. Each massive data set, including the one we actually have ($\tilde{F}_0$) gives rise to a set of potential samples, and implies a sampling distribution used to form an estimate of $\tilde{\theta}_i$. However, only the actual sample and the single estimate $\hat{\theta}$ are realized. If we are to draw conclusions about θ (rather than $\tilde{\theta}_0$) using only $\hat{\theta}$, we must account for the fact that there are now two sources of variation: one due to randomness in drawing our actual sample from the massive data set we actually have ($\tilde{F}_0$), and one due to randomness in drawing the massive data set we have from the population, F .

In Figure 1 we require knowledge of how our actual sample was obtained from the population in order to specify the sampling distribution of $\hat{\theta}$. In Figure 2 we require knowledge of how our actual sample was obtained from our actual massive data set, and also how our actual massive data set was obtained from the population. Notice that Figure 1 is actually embedded in Figure 2; in the terminology of the latter, the former gives a confidence interval for $\tilde{\theta}_0$,

not θ . In fact, the appropriate sampling distribution of $\hat{\theta}$ it as an estimate of θ is a mixture of all the distributions on the left side of Figure 2. Thus, it is crucial to understand and properly model the sampling procedures that take us from population to massive data set, and from massive data set to sample.

When faced with a massive data set, an analyst must first determine whether it is “massive” in the sense that it needs to be treated according to the model in Figure 2. The question really is one of model specification: is the goal to make an inference about the massive data set itself, or about the population from which it came? There is merit in both, and the answer depends critically upon the substantive problem at hand.

Massive data sets tend to be collected opportunistically from their parent populations, rather than according to a sampling design. For instance, NASA's Earth Observing System (EOS) remote sensing satellites are in polar orbit, and always observe the Earth within about 20 min of the same time of day, local time. A host of physical requirements determine orbit characteristics, instrument design, and data collection strategies before statistical representativeness is considered. If the quantity of interest is, say, column integrated atmospheric water vapor at 10:30 a.m. (and the overpass time is nominally 10:30 a.m.) then all is reasonably well because the massive data set $\tilde{F}_0$ turns out to be representative of the population, F . If, however, the quantity of interest is column integrated atmospheric water vapor over all times of day, $\tilde{F}_0$ is not representative of F . The need to account for the relationship between F and $\tilde{F}_0$ is generally not as well understood in massive data set analysis as is the need to account for the relationship between $\tilde{F}_0$ and samples drawn from it.

In many cases massive data sets result from (a) automated collection of vast amounts of information long before specific scientific hypotheses are formulated and (b) situations where it would be impossible to go back and collect the data over again if they were later found to be wanting. We call this the *kitchen sink* strategy: get everything you can (including the kitchen sink) now because you don't know if you'll need it eventually or not. For example, in manufacturing semiconductors, structures are built directly into chips that report on aspects of chip health for quality control purposes [1]. No formal statistical hypothesis underlies the decision to collect these data – just a general sense that the information will be useful.

Once the chips leave the manufacturing facility they can't be brought back, retooled, and reevaluated.

Modern technology makes it relatively easy to collect these observational data sets when the proper situations present themselves, but those situations are not generally repeatable or under experimental control. The tendency is to compensate with massiveness when opportunities do appear. Moreover, one does not generally know, at the time of collection, all the uses to which the data will be put, so the representativeness of $\tilde{F}_0$ for specific subsequent purposes is not clear.

Massive Data Set Analysis

Most existing work on massive data set analysis focuses on drawing conclusions about them rather than making inferences about their underlying populations. The broad area known as *data mining* is largely concerned with this problem, and in fact one definition of data mining is automated descriptive analysis of massive data sets. If massive data sets are thought to be representative of their underlying populations, then conclusions carry over, although uncertainty estimates are rarely, if ever, provided. When they are, uncertainties presented are usually determined by within-sample cross-validation, not by comparisons (see **Global Warming; Volatility Smile**) to the sampling distribution relevant to the underlying population (see Figure 2).

Nonetheless, a vast body of statistical, data mining (see **Early Warning Systems (EWSs) for Predicting Financial Crisis; Risk in Credit Granting and Lending Decisions: Credit Scoring**), and algorithmic work has been done to develop methods for understanding and quantifying structure in massive data sets. The lines separating these research areas are not crisp, but the distinctions are useful for discussion purposes. In this article we focus on approaches that are purely statistical in the sense that they have lineage reaching back to the fundamental statistical concept of data reduction.

The most direct link to data reduction arises from using probability models as descriptive summaries of data sets. For purposes of characterizing and ultimately understanding data structure, the model is a descriptive device. Although all data sets are discrete, models may be continuous if viewed as idealized descriptors, and so density estimation methods provide an important set of tools.

There is a large literature on density estimation (see **Enterprise Risk Management (ERM)**), but less on the problem of density estimation with massive data sets. Scott and Masahikow [4] provide a good discussion of the problem, and offer a potential solution called the *polynomial histogram*. Another line of work (Cheng *et al.* [5] for example) concentrates on scaling up with a “quick kernel density estimator” (see **Bayesian Statistics in Quantitative Risk Assessment**) that leverages a computational simplification obtained by constructing a pseudo-data set from the original data. Bayesian analysis methods that simulate posterior distributions such as Markov chain Monte Carlo (MCMC) (see **Non-life Loss Reserving; Reliability Demonstration**) are computationally expensive, so Ridgeway and Madigan [6] use a subset of the data for the computationally demanding portion. The rest of the data are used *via* importance sampling to reweight the initial MCMC draws. Similarly, Braverman *et al.* [7] use samples from a massive data set to construct adaptive histogram bins, which are then used to summarize all the raw data.

These last three examples all use some subset, subsample, or transformation of the original information to provide an initial solution, which is then sharpened by a computationally simpler step that incorporates the rest of the data. They all aim to approximate the distribution of the original data, either parametrically or nonparametrically. Distribution estimates can then be used to answer a wide range of questions about data structure.

Cheng *et al.* and Ridgeway and Madigan provide functional distribution estimates, nonparametric and parametric respectively. Braverman *et al.* produce a set of representative points, associated weights, and measures of variability that can be viewed as a coarsened representation of the original empirical distribution, or as a smaller compressed version of the original data that approximately retains their distributional characteristics. This is not unlike the method of data squashing [8, 9] which provides a representative set of points and weights such that characteristics of the likelihood function are preserved, and inferences based on squashed data are the same as inferences based on the original data. Pan *et al.* [10] define “the representative subset” as a “small subset of the original dataset that captures most of the original information compared to other subsets of the same size and has a low redundancy”.

They use an algorithm based on information-theoretic measures to determine such a subset.

There is a strong connection between these data reduction approaches and quantization in signal processing. Quantization, which is a form of source coding, contemplates a stream of random variables from an unknown probability distribution called an *information source*. Each realization, or signal, is to be transmitted over a channel with finite capacity. This means that signals can't be transmitted with perfect precision because their exact binary representations have too many bits. Thus, they must be quantized: each distinct potential realization is assigned to a group represented by a single value called a *codeword*. For each signal, only its group index (in binary form) is transmitted, and at the receiver the index is replaced by the codeword for the group as an estimate of the original signal. Codewords are normally the centroids of their groups. The number of groups and the assignment of potential signal realizations to them determine the average number of bits needed for transmission, and this must be less than the capacity of the channel.

The average number of bits needed for transmission is measured by the entropy (see **Expert Judgment**) (H) of the distribution of codewords. The error of the reproduced signal stream is measured by distortion (Δ), the average squared distance between the original signals and their codewords. The entire system is characterized by the entropy-distortion pair, and for every information source there is a theoretical curve called the *rate-distortion function* (see **Insurance Pricing/Nonlife; Risk Measures and Economic Capital for (Re)insurers**) which gives a lower bound on entropy as a function of distortion [11].

If we identify the signal stream with random draws from a data set, then we can say that the rate-distortion function is a descriptive characteristic of the data set. Further, we define data reduction as reduction in entropy from that of the original data. If every raw signal is unique (to infinite precision), then data reduction is $\log_2(N) - H$, where N is the number of data points. Thus there is a one-to-one relationship between data reduction and entropy.

The rate-distortion function provides a gold standard against which to judge any data reduction scheme that can be framed as a form of quantization. This includes, for example, clustering algorithms, and in fact some of the original quantization algorithms

in signal processing effectively perform clustering on training sets taken from the signal stream [12].

Braverman *et al.* appeal explicitly to this formalism, but the direct density estimation methods discussed earlier do not. Nonetheless, it is interesting to contemplate how the rate-distortion paradigm could be used to evaluate these techniques. For instance, data squashing suggests that distortion should be evaluated not with respect to the original data, but with respect to the quality of a particular estimator. Polynomial histograms, quick kernel density estimators, and Ridgeway and Madigan's ultimate estimates of posterior distributions could be evaluated with respect to a distortion measure for differences between distributions.

Understanding Large-Scale Structure

In many fields of study where massive data sets exist, one goal is to understand or describe what the data have to say about general relationships among important variables on large scales. The task is difficult because a key feature of massive data sets is that they provide details of *local* structure on a global scale. That is, massive data sets are not just big – they are complex, providing fine-scale information globally. Simple forms of data reduction that throw away fine-scale information thwart the effort.

As an example, consider the application with which the author is most familiar: massive remote sensing data sets. These data sets provide detailed information at high spatial and temporal resolution about structure and changes in the atmosphere. They typically include a large number of variables, and relationships among these variables are of primary importance (e.g., for the study of climate change). Moreover, phenomena of interest exist at various scales: hurricanes are transient in time and space, but oscillations like El Nino cover much larger spatial areas and occur over longer time periods.

The simplest way to reduce such a data set is to perform what is known as *gridding* in geoscience. One fixes attention on some spatial and temporal scale of interest, say monthly time resolution and 1° latitude by 1° longitude spatial resolution, and populates each space–time grid cell with the average values of the variables of interest. Gridding has the advantage of being simple and easy, but also has obvious drawbacks. Distributional information within grid cells is lost, including the very information that

might be most important: information about high-order relationships among variables.

Nonetheless, the essential idea of stratifying data according to values of well-understood variables and then describing these data distributions within strata is useful. We call this *chunking* the massive data set. In the remote sensing example, chunking is done using space and time. The relationship between two space–time grid cells is intuitive, and it’s easy to understand a comparison between data distributions defined in this way. Whether one uses simple means or more sophisticated data reduction methods, the idea is the same. Further, if the initial chunking is done at a fine enough level (e.g., daily, one-half degree latitude and longitude), then data distributions at coarser levels can be formed by aggregation provided the statistics chosen to describe the data are amenable.

In view of this strategy, large-scale structure in massive data sets may be understood as the evolution of the empirical distributions across suitably chosen chunks, including chunks that span different resolutions of aggregation. While this perspective follows naturally from working with spatial and temporal data, the idea can found elsewhere [13, 14] as well. Many methods have been proposed to estimate or describe empirical distributions. Some of these were discussed earlier in this article. Others include clustering algorithms [15], regression models [13], and sketches [16, 17].

Understanding large-scale structure in massive data sets requires compromise between data reduction and the need not to presume too much so the data may speak for themselves. Of course, this is the classic tension in all of statistics, so in many ways massive data sets are just the latest challenge in the ongoing evolution of the field. Some argue that the inevitable increase in computer power will take care of the problem eventually. However, data collection will always be easier than analysis, and so data set size will always outstrip computational resources. Massive data sets and analysis techniques for them will continue to be part of the statistical landscape no matter how large and powerful computers become.

What Challenges and Benefits Do Massive Data Sets Pose for Risk Analysis?

Massive data sets pose the same challenges for risk analysis that they pose generally in other areas, but

they also offer the possibility of mitigating risk by virtue of their complexity and comprehensiveness. The general pitfalls of massive data sets include difficulties in analyzing them because of their size, and the possibility that some important piece of information will be overlooked. On the other hand, the notion that massive data sets allow one to study local or fine-scale behavior on a global scale offers tantalizing opportunities to reduce risk.

For example, in climate studies a basic objective is to improve understanding of the behavior of the various components of the climate system. One such component is the transport of aerosol particulate matter around the world. Aerosol transport models codify the best understanding of how this complex system works, and how it changes in response to changes in other parts of the climate system. At the same time, massive observational data sets are being acquired by satellites to be used to help improve the models.

How do we determine whether the models are correctly representing the movement of aerosols around the world? This is an important question because the radiative effects of aerosols are among the most uncertain of the entire climate system [18]. Aerosol transport models can be used to produce massive synthetic data sets, and a natural starting point for model improvement is to ask whether the large-scale structures present in the satellite data are reproduced by the models.

Perhaps more importantly, can the satellite data sets be used to uncover why discrepancies exist between the model predictions and the data? The fine-scale detail in the observations play a crucial role: it is the ability to drill down to fine scales that makes massive data sets so useful. They preserve both large-scale context and fine-scale information. The trick is to get at both, so methods for understanding large-scale structure in massive data sets must preserve this link. If they do, then analysts can grasp the overall landscape and assimilate it as a guide to the more detailed information at finer levels.

In this example, improved models indicate better physical understanding and a consequent ability not just to make better predictions in the future but also to improve adaptation and mitigation strategies. This in turn reduces health risks in areas heavily impacted by aerosols, and increases ability to respond to climate impacts of changing distributions of various aerosol types.

This is just one example of how massive data sets can reduce risk in areas of fundamental importance to society. There are, of course, many others drawn from other fields. In any case, our ability to understand our world and improve our quality of life rests in no small part on data collection and analysis. Massive data set analysis plays a very important role in this endeavor, and will continue to be an area at the forefront of statistical research.

Acknowledgment

The research described in this article was carried out at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with the National Aeronautics and Space Administration.

AMY J. BRAVERMAN

Use of Decision Support Techniques for Information System Risk Management

Identifying and understanding security risks for information system design or evaluation is very challenging. Making decisions about accepting or mitigating these risks through a rational, traceable, and understandable process is even harder. One reason is because adversaries are numerous – talented and motivated to attack information systems. Their motives can include harming the missions or functions supported by the information system, making a profit, enacting revenge, or just having fun. Another reason that analyzing security risks is hard is that adversaries observe the actions of the information system users and defenders and change their tactics in response to enhancements made to the system. In addition, information systems are becoming more complex and interdependent. Rapid changes in hardware and software make it nearly impossible to find and fix all system vulnerabilities, which can be introduced or exploited at many points in the system's life cycle.

Confounding the difficulty of security risk analysis are the numerous stakeholders involved in any information system. Stakeholders are individuals or organizations that have a vested interest in the information security and its solution [1]. Stakeholders such as users, system administrators, and system designers care about the system and have multiple and often conflicting objectives. System certifiers and accreditors are stakeholders too, and they need the appropriate risk information to make sound decisions about the system. Other information system stakeholders can include customers, maintainers, bill payers, regulatory agencies, sponsors, and manufacturers [2]. Ideally, one would like to include the points of view of all stakeholders in any decision about the security risks associated with an information system.

Quantitative risk assessments for information systems have many benefits. However, they also have their disadvantages. Both the advantages and disadvantages are discussed below.

The Advantages of Quantitative Risk Analysis for Information Systems

The largest benefit of a quantitative information system risk analysis is the ability to help stakeholders make risk-informed decisions by explicitly and clearly measuring risk and design trade-offs. Some quantitative methods, such as the multiple objective decision analysis (MODA) techniques described later, provide a rigorous, traceable, repeatable, and understandable process for communicating quantitative risk and design decisions to stakeholders and decision makers. Another advantage of quantitative risk analysis techniques is that they account for uncertainty [3], which is always a concern when making risk-related decisions. There are several good examples of quantitative information system risk assessment methods including Buckshaw *et al.* [4], Butler [5], and Hamill [6, 7]. These techniques have been successfully used to support multiple, large-scale network designs.

The Disadvantages of Quantitative Risk Analysis for Information Systems

The biggest disadvantage of quantitative security risk assessments for information systems is that they are hard to correctly develop, analyze, and explain. Quantitative risk assessments require experienced quantitative risk analysts, resources (including access to information system experts and threat experts), and time to complete a risk analysis. There are numerous pitfalls that a risk analyst needs to avoid to ensure that his/her quantitative risk recommendations are meaningful and valid [8]. One major pitfall is mistaking semiquantitative risk models for being quantitative. Semiquantitative models often translate qualitative scales into numeric scales. For example, the words “high”, “medium”, and “low” might be given the numbers “1”, “2”, and “3”. Often, these scales are ordinal, meaning that the only information they contain is a numeric rank order of benefit. This limits the legitimate mathematical operations allowed on these numbers [9]. These models can present a false appearance of precision and objectivity, and may encourage a level of confidence that may not be fully justified [10]. A majority of the information system risk assessments observed by the author can be described as semiquantitative. Some additional pitfalls include misunderstanding

of the meaning of weights used in the quantitative assessment [11], improperly measuring the effect of risk on the stakeholders' mission, and treating high-impact, low-probability events as the same as low-impact, high-probability events.

The remainder of this paper assumes that the reader values a quantitative risk assessment approach, and describes more about the people, processes, fundamental concepts, and mathematical interpretations of risk. The first section reviews the different stakeholders and their risk preferences. To help the stakeholders make risk-informed decisions, they need to understand some basic risk concepts, which are described in the second section. A formal process to analyze and adjudicate risk decisions is discussed in the third section. Finally, the fourth section describes different methods for quantitative risk modeling and their advantages and disadvantages.

Decision Support Stakeholders

Information systems have many stakeholders who are interested in the successful design, certification, and operation of the system. However, each individual stakeholder has his/her own wants and needs from the information system, and often these objectives conflict with the objectives of other stakeholders. For example, a user might want a system that is easy to use and has a great deal of functionality. However, a system administrator might want to enforce strong passwords (which users find harder to use) and remove instant messaging (a capability that users may desire) in order to remove vulnerabilities that can be exploited by network attackers. The major concerns and needs of all of the stakeholders need to be considered in the risk model. Individual stakeholders may not get the system that is best for them, but they may better understand why design decisions and trade-offs had to be made to satisfy the other stakeholders (*see Experience Feedback; Multiattribute Modeling*).

Users

Users are the individuals for whom the information system was, is, or will be designed. Users have a mission to perform and the information system should enable them to perform their mission in an effective and efficient manner. The information system should

be available and provide accurate information to only authorized users at all times, even when under attack. A typical user is primarily interested in an easy-to-use, functional solution. Confidentiality of data, availability of data and services, and integrity of data are desired, or even required, but only in a transparent manner.

System Administrators

System administrators are individuals who actively manage and maintain the services and configuration of the information system. They want to keep their system available and as easy to use as possible, but not at the cost of network security. Administrators are very busy and in high demand. They look for security solutions that do not take a lot of time to review or maintain. Security solutions that do require too much attention (e.g., audit logs that require manual review or intrusion detection systems that provide too many false positives) may be ignored or not used at all.

System Owners

System owners are individuals who are accountable for accomplishing a specified mission using the services of an information system that they own and operate. They have to balance the needs of the operating organization with the efficiency of the user. They have one eye on the cost and the other on the schedule. The owner not only wants to make the user happy but is also willing to give up a little functionality and ease of use, if it means that the network will be safe from attack. Owners are often the decision makers for information system risk and design decisions.

Decision Support Basic Concepts

There are four basic concepts for considering the risk to a complex, interconnected information system:

1. **Interdependency of system components**

The first concept involves the fact that in networks there are complex interdependencies of components that are not easily captured in system descriptions and models. Small perturbations in the complex networks, channeled through these subtle interdependencies, can create conditions for cascading failures that can

lead to failures throughout the system, such as loss of network connectivity.

2. Value measurement

The second concept is that we can measure the value of an information system to the multiple stakeholders. Values are simply things that we care about [12] or desired characteristics of the system and its services. Simple mathematical techniques exist that allow one to measure value across many performance and security measures.

3. Value trade-offs

The third concept is that in most cases an increase in performance in one function of the system often leads to a decrease in value of another function. The most common example is that, in most cases, any increase in performance comes at a monetary cost. Thus increasing the value in one area (performance) decreases the value in another area (cost). Often, increases in the level of security of an information system are accompanied by the loss of a functionality. One might remove an instant messenger feature in order to remove an exploitable vulnerability, but this will result in the loss of a rapid, user-friendly form of communication. The system owner or designer will have to make a trade-off decision, carefully weighing the difference in value of one design choice over another.

4. Return on investment

The fourth basic concept is return on investment (ROI). ROI measures the benefit that is returned for the investment (the costs of purchasing or implementing risk-mitigating strategies). This means that we need to consider the benefits and the costs.

Interdependency of System Components

An important concept that should be considered in any risk and design effort is the concept of cascading failures. A cascading failure is a phenomenon where a single disrupting event, such as the failure of a router, causes the entire network to fail. When the first node fails, its load is transferred automatically to other nodes. If one of these replacement nodes becomes too overloaded, it also fails, causing its assigned load, plus the additional load of the first node, to be assigned to other nodes. This continues until an entire network collapses. Cascading failures can and do happen. Examples include a 1986 Internet congestion

collapse, the 1996 power outage in western United States, and probably the August 2003 power outage in the northeastern United States [13]. Cascading failures are often not recognized by designers because of the use of static models that might only examine the effects of a nearest neighbor. However, dynamic models and simulations exist that can be used to stress the network under various attack scenarios.

Value Measurement of an Information System

A key concept for integrating risk analysis and design analysis is the idea of maximizing the benefit of an information system. An information system has value because it provides important information and services. Risk-mitigating designs provide value by ensuring a secure and available system in a hostile and malicious environment. In some cases, the decision might be easy if there is only one objective to worry about, such as minimizing cost. However, often there are several competing objectives, such as security risk, cost, schedule, and performance. In addition, there are many stakeholders, each with his/her own sets of assumptions and preferences across those objectives. One can create a value model to help determine the overall worth of any design choice, given the values and objectives of an organization. By using a value model, one can easily trade-off concepts that are greatly different such as security risk and system's ease of use.

Value Trade-offs

Most information system design choices require some form of a trade-off. The simplest example would be that an additional capability or enhancement to an information system will incur a cost or schedule increase. A trade-off analysis can help determine if the benefit of the choice is worth the cost considering all stakeholders. However, some trade-off decisions are not so easy to make since they involve complex issues besides cost or schedule. For example, the network owner might be faced with a decision on how to implement the rules of an intrusion detection system. Increasing the sensitivity of an automated intrusion detection system will help ensure that more adversary attacks are detected and stopped. However, increased sensitivity might mean that there are many more false positives. This can cause a decrease in network performance and can inure system security engineers to

real attacks. A decision analysis framework is tailored to help decision makers explicitly measure the trade-offs required, especially if the trade-offs are hard to measure.

Return on Investment

ROI can be defined as the profit from an investment divided by the money invested. For an information system, ROI can be more generally defined as the value provided by investments in the information system (e.g., capabilities gained) divided by its cost. It is possible to measure the ROI of increased security to an information system by determining the cost of the countermeasures and estimating the reduced operating and insurance costs from finding and fixing a network intrusion. However, some organizations are not able to measure ROI using monetary gains. For example, government organizations need to measure the benefit (value) of the network in terms of keeping secrets safe, ensuring the availability of critical data and services, and assuring that sensitive data has not been altered. These organizations can measure ROI by determining the overall value of the architecture (availability, accuracy, protection, and confidence in the information and services of the system) before and after a risk-changing design. Essentially, the analysis is a system-level trade-off study where the value of the architecture takes into account several individual benefits and cost trade-offs.

Decision Support Processes

Once the information system stakeholders understand the basic decision concepts, they need to fit the concepts into a decision process. Many information systems of large organizations must undergo a certification and accreditation process before they become operational. Certification is the comprehensive evaluation of technical and nontechnical features of an information system to establish the extent to which a particular design meets a specified security requirement. Often the certifier of the system will mandate technical evaluations of the system to document the certification. An accreditor is the official with the authority to formally assume responsibility at an acceptable level of risk. However, the certification and accreditation processes are often viewed as “a

picayune process where auditors inspect reams of security documentation on an agency’s IT system and infrastructure” [14]. However, quantitative risk modeling can greatly help with the certification and accreditation processes by providing a clear statement of information system residual risk and provide a recommendation for an acceptable level of risk. Additionally, a quantitative risk model can be used to prioritize recommended system design changes or countermeasures on a risk and cost basis.

Certification

The certifier determines whether a system is ready for certification and conducts the certification process. At the completion of the certification effort, the certifier reports the status of the certification and recommendation to the accreditation official for an accreditation decision. Often the certifier will evaluate the security compliance and assess residual risk. A quantitative risk assessment can be used by the certifier to identify the overall system risk and determine the best ways to reduce the risk while keeping costs down and having minimal negative effects on the users’ capabilities or the performance of the network. A prevalent philosophy is that the certifier should be independent from both the users and developers. However, any design effort could greatly benefit from having a team member with certification experience who can help design security into the system. Including a certifier on the design team can also help ensure that a system is fully accredited by the time it is deployed.

Evaluation

Certifiers use a variety of evaluation techniques to ensure compliance with security policies. Security test and evaluation teams examine and analyze the safeguards required to protect an information system as they have been applied in an operational environment. Penetration testing and “Red Teams” are techniques used to simulate the activities of a hostile adversary attacking the information system from inside or outside of the network boundary. Tests can also be performed to verify the integrity of the hardware and software throughout the design, development and delivery, to determine if there are excessive emanations from the equipment and to

verify that no unauthorized connections exist. The evaluators are the primary source of data for the quantitative risk assessment and the risk-management review.

Accreditation

The accreditor assesses the vulnerabilities and residual risk of the system and decides to accredit, give an interim authority to operate, or terminate system operations. Accreditation is the official decision by an information technology management official to authorize operations of an information system and to explicitly accept the risk to organizational operations, assets, or individuals based upon the implementation of agreed-upon security controls. Quantitative risk assessment methods can be of great value to the accreditor by providing a framework for assessing the risk of any system, and across systems, using the same metrics.

Defining Risk for Information Systems

Risk can be mathematically defined as a measure of the probability and severity of adverse effects [15]. Making information system design decisions under uncertainty is a complex undertaking. Compounding the problem is a general lack of historical risk data for most information system problems, as compared to the historical data that is available for an environmental risk assessment. However, in general, most information system risk assessments claim that risk is some function of “threat”, “vulnerability”, and “consequence” (sometimes called *impact*). Different models interpret and measure these three parameters differently. Three techniques seen in risk modeling are qualitative, semiquantitative, and quantitative. Well constructed qualitative models can be very useful, especially for quick, high-level assessments, but are beyond the scope of this section. See Smith *et al.* for a discussion on the advantages and disadvantages of qualitative risk assessments [16].

Quantitative Risk Models

Quantitative risk models for malicious activity can determine risk by considering the “threat” as a probability that an adversary will attempt an attack ($p(a)$),

“vulnerability” as the probability of adversary success given that they attempt the attack ($p(s|a)$), and consequence as the negative effects given a successful attack ($C|s, a$). Two quantitative risk methods include probabilistic risk analysis and MODA.

Probabilistic Risk Analysis. Probabilistic risk analysis assigns probabilities to the $p(a)$ and $p(s|a)$ elements in the quantitative risk model. Consequences are either known or can be assigned a probability over a range of consequences. One can analyze the risk distributions and calculate expected values of the risk. The concept of expected value risk is similar to that of expected value in probability theory – the multiplication of the probability of an event and its outcome value. Essentially, this is the average outcome that one would expect from an attempt of a particular attack. Since attacks generally have a binary outcome (success or failure) one might not even realize the “expected” risk. Mathematically, the expected risk to a system for a particular attack on a given information system, over a given period of time is shown by equation (1).

$$Risk = p(a) \times p(s|a) \times C|s, a \quad (1)$$

The risk of a portfolio of attacks might be the sum of risks over the entire attack space. There are several problems with this formula. First, there is the desire to translate the consequences of risk into a measure of expected annual financial loss. This might work well for some; however, many organizations cannot translate their mission into meaningful financial terms. Even private firms would have difficulty estimating the consequences of a successful penetration of their information systems.

Second, obtaining valid estimates of $p(a)$ for a given time frame is very difficult, often impossible. Adversaries do not often act in predictable ways and will change their behavior, based on changes to the information system’s security.

A third problem is that data for $p(s|a)$ is often historical in nature and biased to attacks that were detected and reported. Ideally, the data for $p(s|a)$ should be forward-looking to address future concerns, instead of reporting past problems that most likely have already been mitigated.

A fourth problem is that the formula above is the *expected* risk. In an expected risk formulation,

rare events that have catastrophic consequences are considered equal in risk to common events that have relatively small consequences. Haimes states that “the expected value of risk fails to represent a measure that truly communicates the manager’s or decision maker’s intentions and perceptions [17]”. In the author’s experience, many decision makers do not agree with expected value risk decisions. This is especially true in military and government organizations. These organizations do not follow expected value decision making, because the impact of a low probability but high consequence computer attack could cripple a nation’s defense or economy. Also, a successful, undetected attack against an information system can have long-term consequences since an adversary can cover his/her tracks and possibly create multiple hidden entry and exfiltration routes inside the system. A quantitative method that was created to mitigate these three problems is a MODA approach [18–20].

Haimes created a method to mitigate the effects of expected value risk analysis called the *partitioned multiobjective risk method* (PMRM) [21]. In PMRM risk is measured, given that the damage falls within specific ranges of probabilities. Instead of just providing the expected value of risk, PMRM allows the analyst to show many ranges of risk, such as “low severity, high exceedance probability; moderate severity, medium exceedance probability; and high severity, low exceedance probability”.

Multiple Objective Decision Analysis (MODA) Risk Analysis. MODA risk assessments, such as the mission-oriented risk and design analysis (MORDA) method [22], were created because of the difficulties in collecting data and assessing risk in a purely probabilistic manner. Instead of providing probabilities of attempt, MORDA assessments seek to characterize attacks in terms of their value [12] or impact to both the attacker and the defender. System security engineers and adversary experts work together to define what makes an attack valuable to an adversary considering measures such as probability of detection, consequences of detection, probability of success given detection, resources expended, probability of attribution, consequences of attribution and payoff given a successful attack. Attacks are scored on these value measures using an interval or ratio scale, which are then translated into attack values. The total attack value to the

adversary is calculated using a weighted sum of the attack measures. If the model meets the required independence assumptions and the modeler uses ratio weights [23], the value is measured using a simple weighted average as shown in the equation (2).

$$v(x) = \sum_{i=1}^n w_i v_i(x_i) \quad (2)$$

where $v(x)$ is the value of the attack to the adversary, $i = 1$ to n is the number of the value measure, e.g., “payoff” or “resources expended”, x_i is the score of the attack on the i th value measure, e.g., “high” or “low” payoff, $v_i(x_i)$ is the single dimensional value of a score of x_i , e.g., “high” payoff has a value of “1”, w_i is the weight of the i th value measure, e.g., weight for payoff = 0.25, and $\sum_{i=1}^n w_i = 1$ (all weights sum to 1).

With either the probabilistic risk model or the MORDA model, risk to an information system can be analyzed and reported in a traceable and understandable manner. More importantly, these models can be adapted for use as a design tool for assisting with secure system design and cost–benefit trade studies (*see Reliability Optimization; Clinical Dose–Response Assessment*).

Semiquantitative Risk Analysis

Semiquantitative risk analysis for information systems is a widely used method to simplify the risk assessment process using easy to understand scales and mathematics. A commonly used model is a variant of the probabilistic risk calculation discussed earlier. However, instead of probabilities, ordinal or interval scales are used to measure threat, vulnerability, and impact. For example, these three characteristics might be measured on a 1–100 scale. The risk to the system is determined by taking the product of the three risk scores as shown in equation (3).

$$Risk = threat \times vulnerability \times impact \quad (3)$$

This technique has one major benefit – it is very simple because it allows for data collection using natural language. However, there is great debate as to the meaning of the resulting number and the validity of the calculation. Often semiquantitative risk assessments use interval scales. Multiplication and division

on the individual measures using interval scales is not permitted [24]. MODA risk assessments avoid this issue because interval scales can be multiplied by a constant, which is MODA's ratio weight. Semiquantitative risk methods that perform mathematical operations on ordinal scales are of great concern. Risk assessments using ordinal scales cannot even use addition and subtraction. In one study, risk calculations using ordinal scales created an error of over 600% in the model [25]. Semiquantitative risk assessments should be avoided on account of these concerns.

Summary

In this paper, we have discussed the advantages and disadvantages of quantitative risk assessments for information systems. We have also discussed the stakeholders, basic decision support concepts, decision support processes, and measurement of risk. There are great benefits in performing a quantitative risk assessment. Mathematical techniques can account for the multiple, and often conflicting desires of many stakeholders and provide the certifiers and accreditors with the necessary data to make complex design trade-off decisions. These decisions can be made through a rational, traceable, and understandable process. Semiquantitative risk assessments have mathematical problems that prohibit their reliable use for risk assessments.

DONALD L. BUCKSHAW

Utility Function

Suppose you are asked to choose between two projects as in Figure 1.

This is a difficult choice as we must consider both probabilities and associated outcomes to identify the preferred project.

Utility function and expected utility theory [1] aid a decision maker in making choices among projects (alternatives or options) whose outcomes are uncertain at the time of decision making. The basic idea is to use the utility function of the decision maker to convert outcomes into utilities and then to compute expected utility for each project. The project with the highest expected utility is then chosen. We will answer the following questions:

1. What is the justification for using expected utility as a criterion for choosing among alternatives?
2. How do we assess utility function?
3. What are some behavioral properties of utility function?

Expected Utility

Consider a set of outcomes or consequences, X . Let P be the set of probability distributions on X . Let us assume X is finite or P is the set of all simple probability measures on X . An element of P is denoted by lower case letters p, q, r , etc. and that of X by x, y, z , etc. In our example, project A is represented by p and project B by q . Let us use the notation $\succsim$ to denote “preferred or indifferent to”. We need a concept of compound lottery, $\alpha p + (1 - \alpha)q$, which also belongs to P and denotes that the lottery returns p with chance α and returns q with chance $(1 - \alpha)$, $\alpha \in [0, 1]$.

The following axioms, which address the decision maker’s preferences for lotteries in P , justify the use of expected utility as a criterion for choosing among lotteries in P .

Axiom 1 For all $p, q, r \in P$, (a) $p \succsim q$ or $q \succsim p$ and (b) if $p \succsim q$ and $q \succsim r$, then $p \succsim r$. The first part of this axiom shows completeness and the second part shows transitivity.

Axiom 2 For all $p, q, r \in P$ and $\alpha \in [0, 1]$, $p \succsim q$ implies that $\alpha p + (1 - \alpha)r \succsim \alpha q + (1 - \alpha)r$. This is

the key axiom of expected utility theory and requires that if one prefers p over q , then one should prefer the compound lottery with α chance of yielding p and $(1 - \alpha)$ chance of yielding r to the compound lottery with α chance of yielding q and $(1 - \alpha)$ chance of yielding r . Since the common outcome r is obtained with common probability $(1 - \alpha)$ in both compound lotteries, the choice between two such compound lotteries is determined only by the preference between p and q . This axiom is called the substitution or independence axiom. Normatively, this axiom is very appealing, but people often violate it and some extensions of expected utility theory are based on relaxing this axiom.

Axiom 3 For all $p, q, r \in P$, if $p \succsim q \succsim r$, then there exists $\alpha \in [0, 1]$ such that

$$\alpha p + (1 - \alpha)r \sim q \quad (1)$$

This is called the continuity or Archimedean axiom. This axiom ensures that every intermediate lottery can be made equivalent (in preference) to a compound lottery between the more desirable and less desirable lotteries by suitably choosing α . The above three axioms lead to a remarkable result.

Theorem 1 A binary relation $\succsim$ on P satisfies Axioms 1–3 if and only if there exists a function $u : X \rightarrow \mathbb{R}$ such that $p \succsim q$ if and only if:

$$\sum_{x \in X} u(x)p(x) \geq \sum_{x \in X} u(x)q(x) \quad (2)$$

Further, u is unique up to a positive linear transformation. In our example, project A is preferred or indifferent to project B if and only if $0.35u(42) + 0.23u(209) + 0.42u(611) \geq 0.61u(153) + 0.39u(502)$. The choice between complicated lotteries is reduced to a simple calculation if we can somehow specify the utility function, u .

Assessing Utility Function

We now discuss two methods for eliciting a utility function from a decision maker. Broadly speaking, a utility function reflects the risk attitude of a decision maker and therefore will be unique to each individual. Consider monetary payoffs in the range x_0 to x^* , where x_0 is the worst possible payoff and x^* is the best possible payoff in a given decision context.

Figure 1 A sample probability choice problem

Certainty Equivalent Method

The certainty equivalent of a lottery p is the amount, x_p , such that a decision maker is indifferent between receiving the guaranteed payoff x_p or the lottery p . We denote $x_{0.5}$ as the certainty equivalent of a lottery with $(x^*, 0.5; x_0, 0.5)$, which is a lottery that yields x^* with a 0.5 chance and x_0 with a 0.5 chance.

We set $u(x^*) = 1$ and $u(x_0) = 0$. Therefore, $u(x_{0.5}) = 0.5u(x^*) + 0.5u(x_0) = 0.5$ by the expected utility rule. Now, we have three points on a utility curve. To obtain $u(x_{0.75})$, we use a clever trick. We know that $(x^*, 0.75; x_0, 0.25) \sim (x^*, 0.5; x_{0.5}, 0.5)$ as $0.75u(x^*) + 0.25u(x_0) = 0.5u(x^*) + 0.5u(x_{0.5})$. Therefore, we simply seek the certainty equivalent of a 50–50 lottery between x^* and $x_{0.5}$ and this certainty equivalent provides us with $x_{0.75}$. Similarly, we seek $x_{0.25}$ by eliciting the certainty equivalent of the lottery $(x_{0.5}, 0.5; x_0, 0.5)$.

We now have utilities of five outcomes – $u(x_0) = 0$; $u(x_{0.25}) = 0.25$; $u(x_{0.5}) = 0.5$; $u(x_{0.75}) = 0.75$; $u(x^*) = 1$ – in the desired range $[x_0, x^*]$. We can now find a curve through these points. Notice that the certainty equivalent of a 50–50 lottery between two outcomes is easier to obtain than a direct choice between two complicated lotteries, such as projects A and B in our example. Thus, by seeking answers to some simple questions, we can calculate the preference for more complicated lotteries. We cannot do away with the preferences entirely, but by using expected utility theory we can greatly simplify the choice process.

Probability Equivalent Method

For the certainty equivalent method using 50–50 lotteries between two outcomes, we had essentially fixed the utility levels at 0, 0.25, 0.5, 0.75, and 1 and sought the sure outcomes that had those utilities. For the probability equivalent method, we fix the outcomes $x_0, x_1, x_2, x_3, \dots, x^*$ and seek utilities for

each x_i . Thus, if outcomes are on the x axis and utilities are on the y axis, then the certainty equivalent method fixes some points on the y axis and seeks corresponding points on the x axis. The probability equivalent method fixes points on the x axis and seeks corresponding points on the y axis. To obtain the utility of outcome x_i we simply seek p_i such that $x_i \sim (x^*, p_i; x_0, 1 - p_i)$. Now by the expected utility rule $u(x_i) = p_i$. Depending on the accuracy desired, we elicit utilities for several points and then plot a curve through these points.

Behavioral Properties

Suppose you are offered a choice between a lottery p and a sure outcome equal to the expected monetary value of lottery p . If you prefer the expected monetary value to the lottery and do so for all lotteries defined over the range of interest $[x_0, x^*]$, then you are *risk averse* in the range of interest. An immediate implication of risk aversion is that your utility function will be concave. For a risk averse decision maker, knowledge of the utility function at a few assessed points restricts the possible utility values at other intermediate points (see [2]).

A special case of risk aversion called *constant risk aversion* is often used in applications. Suppose a strictly risk averse decision maker is indifferent between receiving a sure outcome x or a lottery p . Now let us add a constant amount Δ to all outcomes of lottery p . If the decision maker is indifferent between the modified lottery $p + \Delta$ and the sure outcome $x + \Delta$ for all Δ , then the decision maker is constantly risk averse within the relevant range of outcomes. The only utility function appropriate for this hypothetical person is exponential. Suppose $x_{0.5} \sim (x^*, 0.5; x_0, 0.5)$, then this one judgment is sufficient to specify the utility function for the constantly risk averse decision maker. Suppose, $x^* = 100$, $x_0 = 0$ and $x_{0.5} = 40$; then,

$$u(x) = \frac{1 - e^{-0.8223x/100}}{1 - e^{-0.8223}} \quad (3)$$

Note that at $x = 40$, $u(40) = 0.5$ as desired.

Suppose u is twice continuously differentiable. Let u' be the first derivative of u and u'' be the second derivative of u . Note that $u' > 0$ if u is strictly increasing (more money is preferred to less) and $u'' \leq 0$ if u is concave (or < 0 if u is strictly

concave). Pratt [3] defined a measure of risk aversion as follows:

$$R(x) = -\frac{u''(x)}{u'(x)} \quad (4)$$

For the constant risk aversion case in which the utility function is exponential, $R(x)$ is a constant. For decreasing risk aversion, relative risk aversion, and comparison of risk aversion for two decision makers, see [3].

The risk aversion property though useful in analysis and applications is not universally accepted as an accurate description of people's behavior. Kahneman and Tversky [4] have demonstrated that people are, in fact, risk seeking for losses, as they do not want to accept a sure loss. Thus, people will not accept a sure loss of \$45 and would rather play a lottery in which they may lose \$100 with 0.5 chance, but with an equal chance to lose nothing (\$0). Risk aversion also does not hold for lotteries with small probabilities of very large payoffs.

In summary, if a decision maker subscribes to Axioms 1–3, then he can use maximization of expected utility as a criterion to evaluate choices under uncertainty. The utility function can be assessed by the certainty equivalent or probability equivalent methods. The assessment of utility function is greatly simplified if some further assumptions such as constant risk aversion are made about decision maker's preferences.

Challenges to Expected Utility

Allais [5] provided perhaps the best known challenge to expected utility. Allais's dramatic example involved large sums of money and extreme probabilities. We provide an example from [4] with moderate outcomes and reasonable probabilities.

Situation 1. Which of the following options do you prefer?

- A. a sure gain of \$30; or
- B. an 80% chance to win \$45 and a 20% chance to win nothing.

Situation 2. Which of the following options do you prefer?

- C. a 25% chance to win \$30 and a 75% chance to win nothing; or
- D. a 20% chance to win \$30 and an 80% chance to win nothing.

The model preference in experimental setting is: $A \succ B$ and $D \succ C$. Such a preference pattern is inconsistent with the expected utility model. To see this observe that $A \succ B$ implies that $u(30) > 0.8u(45) + 0.2u(0)$. However, $D \succ C$ implies that $0.25u(30) + 0.75u(0) < 0.2u(45) + 0.8u(0)$, or $u(30) < 0.8u(45) + 0.2u(0)$.

Since $u(30)$ cannot simultaneously be greater as well as less than the number $0.8u(45) + 0.2u(0)$, there can be no utility assignment that will permit such a preference pattern.

The above example represents a violation of the substitution principle (Axiom 2). To see this, we define option A as p and option B as q . Let α be 0.25 and r be 0. By Axiom 2, $p \succsim q$ if and only if $0.25p + 0.75r \succsim 0.25q + 0.75r$, which is the same as requiring $A \succsim B$ if and only if $C \succsim D$.

There has been a debate in the literature as to whether a rational person would change his mind upon introspection and modify his preferences to be consistent with the expected utility model. It can, however, be asserted that unaided choices of even reasonable and well-trained people do not satisfy axioms of expected utility. Thus, as a descriptive model of behavior, the expected utility model needs modification. Most, if not all, scholars agree that Axioms 1–3 of expected utility theory are normatively compelling. The expected utility model has been used in numerous applications and provides a foundation for decision and risk analysis.

Subjective Expected Utility

Value at Risk (VaR) and Risk Measures

Generally speaking, risk is the possibility of missing an organization's objectives because of external events or internal actions. Hence, risk is strongly related to uncertainty and randomness. This is the reason why quantitative risk management mainly derives from mathematical stochastics. A risk measure is a function that quantifies the size of risk contained in a business unit, company, or trading position. The main reason for using risk measures is to support business decisions. An important figure, therefore, is the risk-return ratio that describes how many additional units of risk we have to take to get one additional unit of return. Another application is to determine how many capital reserves a company needs to stay solvent in case of an occurring risk. This especially affects banks and insurance companies for which taking risk is, in fact, their main business.

In this essay, we discuss risk measures with different applications. In the section titled "Traditional Risk Measures", we present traditional risk measures like volatility, shortfall probability (SP) (*see Risk Measures and Economic Capital for (Re-)insurers; Extreme Value Theory in Finance*), and other lower partial moments (LPMs) (*see Axiomatic Models of Perceived Risk; Axiomatic Measures of Risk and Risk-Value Models*) that are used since the mid-twentieth century. In the section titled "Value at Risk", we discuss the value at risk (VaR), which is, at the moment, used to control the market risk of almost every major financial institution in the world. The section titled "Coherent Measures of Risk" describes some mathematical requirements that a so-called coherent risk measure should fulfill and how the presented risk measures meet them. Finally, we give a brief summary in the section titled "Summary".

Traditional Risk Measures

In the sequel, we will study a portfolio with a given price P_0 today and a random price P in the future, e.g., in 1 day. Furthermore, we will continuously use compounded returns $R = \ln(P \cdot P_0^{-1})$, e.g., daily

returns if P is the price in 1 day, to measure the performance of the portfolio.

Volatility and Standard Deviation

The first milestone in risk measurement was made by Markowitz [1, 2]. Before his path-breaking publication, the quality of an investment was mainly measured by its expected return $\mu = E[R]$. Markowitz proposed to use the variance $\sigma^2 = \text{Var}[R]$ to quantify the risk of an investment. Every suitable portfolio should lie on the so-called efficient frontier (*see Asset-Liability Management for Nonlife Insurers*), where no higher return can be generated at the same level of risk. For a further characterization of a probability distribution, we use the concept of central moments. The k th central moment of the random variable R is defined by

$$m_k = E[(R - \mu)^k] \quad (1)$$

For $k = 2$ this is the variance, its square root, the so-called standard deviation or volatility σ measures how widespread the possible returns are. Figure 1 shows the charts of two important indices – the S&P 500 Total Return Index and the JP Morgan Global Government Bond Unhedged USD Index – in the period from January 01, 1988 until December 31, 2005. For the ease of comparison, the starting values at January 01, 1988 are set to 100. We use this data sample in the whole article to calculate the corresponding daily returns and different risk measures.

It is obvious that overall the S&P 500 not only showed a better performance than the bond index, but also had some bad years. On the other hand, the bond index never fell over a long period and shows much less fluctuation. This can be seen in Table 1 showing not only a higher than expected return but also a higher volatility for the stocks. In summary, mean-variance analysis of risky variables is easily calculated and can be very useful to compare different investment alternatives.

However, this method also has disadvantages: variance includes risk and chance to the same degree and thus does not distinguish between gains and losses. Owing to this fact, variance is only appropriate for symmetric distributions. In practice, however, many return distributions are asymmetric. An appropriate measure to check for an asymmetric return

Figure 1 Index charts (January 1, 1988 = 100)

Table 1 Risk measures for sample data (daily returns) based on a portfolio price of $P = 100$

	S&P 500 Total Return		JP Morgan Global Government Bond Unhedged USD, Global	
		p. a.		p. a.
Mean return (%)	0.045	11.105	0.028	6.798
Standard deviation (%)	1.011	15.889	0.376	5.912
Skewness	-0.171	—	0.0326	—
Excess kurtosis	3.962	—	1.771	—
Semivariance	0.004	—	0.001	—
VaR (99%)	2.659	—	0.978	—
VaR (95%)	1.604	—	0.593	—
CVaR (99%)	3.576	—	1.178	—
CVaR (95%)	2.314	—	0.820	—

distribution is called *skewness* and is the third standardized moment of the return distribution, i.e.,

$$s = E \left[\left(\frac{R - \mu}{\sigma} \right)^3 \right] \quad (2)$$

By using an uneven exponent, we keep the algebraic sign of each standardized return leading to a skewness of zero for perfect symmetric distributions. Figure 2 shows the daily returns of the indices in our sample. The S&P 500 has a negative skewness, while the bond index has a smaller positive one. One reason for this is that there are extraordinary high share losses because of natural disasters, political events, or just psychological effects, but rarely gains with the

same dimension. On the other hand, bonds can benefit from panic selling on stock markets. For example, on the first trading day in New York after the terrorist attack on September 11, 2001, the S&P 500 lost over 5% in a single day while the bond index increased by more than 2%.

Another key figure when analyzing market risk is the kurtosis that is similarly calculated as the skewness in equation (2) but with the power of four. The kurtosis gives information about the shape of the return distribution. Most often, we want to compare a variable with the normal distribution that has a kurtosis of three. Therefore we subtract this number from the kurtosis to get the excess kurtosis or just excess. While a negative excess means a low peak with wider “shoulders” (platycurtic), a positive

Figure 2 Histogram of daily returns (January 1, 1988 to December 31, 2005)

value means a narrow high peak and fatter “tails” (leptokurtic). The returns of financial markets are often found to be leptokurtic. Skewness and kurtosis are mainly used to check if an unknown random variable is normally distributed.

Lower Partial Moments – Shortfall Probability and Expected Shortfall

We recognized that there are distributions that are not symmetric and therefore we need a measure that examines only the downside risk of the return distribution, without regarding the chance. For this reason, we discuss a concept that only considers the lower part of the return distribution, the LPMs. They are similar to the central moments in equation (1) but only consider the downside deviation from a given barrier, benchmark return, or target b :

$$LPM_k(R, b) = E[1_{(-\infty, b)}(R) \cdot (b - R)^k] \text{ with} \quad (3)$$

$$1_{(-\infty, b)}(R) = \begin{cases} 1 & \text{if } R < b \\ 0 & \text{else} \end{cases}$$

For $k = 0$ we get the so-called shortfall probability. This simple risk measure was first proposed by Roy [3]. $SP(R, b)$ is the likelihood for the return to fall short of the barrier b and has big relevance in situations where the occurrence of a certain event has an extraordinary effect, e.g., the likeliness of not being able to fulfill contractual duties like the payment of a guaranteed return. From our sample we learn that there has been no trading day where the bond index lost more than 2%. On the other hand, the stock index lost even more than 5% in about 1 day out of thousand.

However, the SP contains no information on the amount of loss in case of missing a target. To do

this, we can use the so-called expected shortfall (ES), which shows the expected amount of loss, given that we fall short of the benchmark b . In mathematical terms we have $ES(R, b) = -E[R|R < b]$ given that $SP(R, b) > 0$. Expected shortfall and LPM are connected by the formula

$$ES(R, b) = SP(R, b)^{-1} \cdot LPM_1(R, b) - b \quad (4)$$

Applied to our example, we recognize that in the few cases where the S&P 500 lost more than 5% in a single day, its expected loss is about 6.3% (see Table 2). That means if there is a crash, it can go down even much further than only the 5%.

Another interesting risk measure is the lower semivariance given as $LPM_2(R, \mu)$. It is calculated exactly like the variance but only considers returns below the mean. Its applications are similar to those of the variance but the problem of asymmetric return distributions is reduced. We get an idea of the size of the return variation below average. However, the meanings of SP and ES are more intuitive and therefore these measures are often preferred. Another reason for this is the fact that these concepts are strongly related to the most famous risk measure – the VaR – which is discussed in the following chapter.

Value at Risk

In the financial sector, managing extreme events plays a major role. Banks and insurance companies can lose immense amounts of money in a single day because of a market crash or natural disaster. Managing extreme risks means building capital reserves to stay solvent in the event of damage. In the banking industry, there exist strong regulations to avoid “bank

Table 2 Downside risk measures for sample data (daily returns)

b (%)	S&P 500 Total Return				JP Morgan Global Government Bond Unhedged USD, Global			
	0.00	−1.00	−2.00	−5.00	0.00	−1.00	−2.00	−5.00
SP (%)	46.152	11.611	2.633	0.113	46.602	0.878	0.000	0.000
LPM_1 (%)	0.340	0.083	0.021	0.002	0.127	0.002	0.000	0.000
ES (%)	0.736	1.718	2.787	6.291	0.272	1.207	–	–

runs” that would destabilize the whole economy. VaR (see **Large Insurance Losses Distributions; Credit Scoring via Altman Z-Score**) is the most widely used measure to quantify extreme risks. We discuss its definition in the first part of this chapter. The second part shows different methods to calculate the VaR. In the last section, we discuss the relations between VaR, the newer concept of conditional value at risk (CVaR), and the traditional concepts of shortfall probability and expected shortfall.

Definition

In the early 1990s, of the last century, financial derivatives became more and more important raising the need for a proper risk management. At the same time the top management requested a 1-day one-page summary of the overall risk position to control the business more properly. The solution was introduced by JP Morgan in 1994 (see e.g. [4] for more details) developing the concept of VaR. Under the name RiskMetrics, the idea was distributed and became standard for almost every major bank in the world. The VaR is based upon the value of a portfolio measured in market prices. It regards the maximum loss that can occur within a certain time horizon Δt (e.g., 1 or 10 business days) with a given confidence level $1 - \alpha$ (e.g., 95 or 99%). The other way round, we experience a loss bigger than the VaR within that period only with a probability of α . Hence, VaR is no more than a quantile of the portfolio return distribution multiplied by the portfolio price. For the ease of exposition we set the portfolio price to 100 in our numerical example. There are several approaches to determine VaR in practice and we will discuss the most common in the next section.

Implementation Methods

All calculation methods for the VaR are based on the distribution of the portfolio return. This return

may be driven by several risk factors, e.g., interest rates, market indices, stock prices, or currencies, and obviously depends on the portfolio weights. The different methods mainly differ by the required knowledge about the portfolio return distribution (see e.g. [5] for more details).

Historical Method. The historical method requires empirical data for the portfolio price $P_t, t = 0, \dots, T$. As already mentioned, these empirical prices may be calculated on the basis of time series of several risk factors. We derive the time series for the portfolio return by

$$R_t = \ln \frac{P_t}{P_{t-1}}, \quad t = 1, \dots, T \quad (5)$$

We get an estimate of the expected return μ and the variance σ^2 per period by

$$\mu \approx \frac{1}{T} \cdot \sum_{t=1}^T R_t \quad (6)$$

and

$$\sigma^2 \approx \frac{1}{T-1} \cdot \sum_{t=1}^T (R_t - \mu)^2 \quad (7)$$

Furthermore, we can derive the frequency distribution F_R of the return in the observed time horizon Δt . In the case that Δt is equal to the frequency in which the empirical data is collected, we get the empirical distribution by simply counting the number of returns smaller or equal than x , i.e.,

$$F_R(x) \approx \frac{1}{T} \cdot \sum_{t|R_t \leq x} 1 \quad (8)$$

In any other case, we first need to transform the time horizon in an appropriate way. Now we can

calculate the maximum loss that might happen in Δt with a certain confidence level α , the VaR per dollar portfolio value (VaR_R) as follows:

$$VaR_R(\alpha) = -\sup\{x | F_R(x) < \alpha\} \quad (9)$$

Consequently, the portfolio VaR is calculated as the VaR per dollar portfolio value multiplied by the portfolio value P , i.e.,

$$VaR(\alpha) = VaR_R(\alpha) \cdot P \quad (10)$$

Note that we always get a positive VaR for a fairly small α . If we let $c_R(\alpha)$ denote the α -quantile of the standardized distribution of the portfolio return, we derive

$$VaR_R(\alpha) = -(\mu + c_R(\alpha) \cdot \sigma) \quad (11)$$

and

$$VaR(\alpha) = -(\mu + c_R(\alpha) \cdot \sigma) \cdot P \quad (12)$$

Now, we use our example again and identify the VaR for mixed portfolios consisting of equity and bonds (Figure 3). As already mentioned, we set $P = 100$ for the ease of exposition.

We see that the portfolio with the lowest risk mainly consists of bonds. The historical method is easy to understand and intuitive but needs some preconditions. First, we need the required data, which is no problem for major indices, but can be difficult for small or illiquid assets and is almost impossible for new ones. Furthermore, we

implicitly assume that we can predict the future only by looking into the past. However, over time, the environmental conditions change and therefore the chosen time period must not be too long, but needs to be a representative sample. In comparison to the historical method, the Monte Carlo simulation (*see Nonlife Loss Reserving; Simulation in Risk Management; Reliability Optimization*) approach uses stochastic processes to generate a multiple of portfolio returns based on statistical or forecasted parameters and may help to overcome the problem of being limited to one historical scenario.

Variance–Covariance Approach. A rather simple and very common method to calculate VaR is the variance–covariance approach, also known as *Risk-Metrics approach* [6]. This method to calculate VaR assumes that the returns of all assets are normally distributed with zero mean and the returns of all assets R_i , $i = 1, \dots, N$ add up linearly to the portfolio return, i.e.,

$$R(\varphi) = \sum_{i=1}^N \varphi_i R_i \text{ with } \varphi_i \text{ denoting}$$

the weight of asset i in the portfolio. (13)

Note that this formula only applies for simple returns and is not true in general for continuously compounded returns. However, if the returns are small, simple, and continuously compounded returns

Figure 3 One day VaR with historical method and variance covariance approach based on a portfolio price of $P = 100$ and daily returns

are approximately the same. Furthermore, the variance of the portfolio return is given by

$$\begin{aligned}\sigma^2(\varphi) &= \text{Var}[R(\varphi)] \\ &= \sum_{i=1}^N \sum_{j=1}^N \varphi_i \cdot \varphi_j \cdot \text{Cov}[R_i, R_j]\end{aligned}\quad (14)$$

with $\text{Cov}[R_i, R_j]$ denoting the covariance of R_i and R_j . Using this information we know that the standardized portfolio return is standard normally distributed and we simply get the VaR by

$$\text{VaR}_R(\alpha) = -c(\alpha) \cdot \sigma(\varphi) \quad (15)$$

and

$$\text{VaR}(\alpha) = -c(\alpha) \cdot \sigma(\varphi) \cdot P \quad (16)$$

with $c(\alpha)$ denoting the α -quantile of the standard normal distribution. Since for huge portfolios it can be quite cumbersome to store, estimate, or update all the required data, RiskMetrics proposed a special method to map the returns of the different assets to a given set of risk factors (see [7] for more details). For these, RiskMetrics and specialized data vendors provide volatility and correlation data. The application of the variance–covariance approach is fast and easy and therefore often applied. Furthermore, there also exist extensions of this approach like the delta normal method and the delta-gamma method for assets that are not normally distributed. In our example, there are deviations between the different methods because the returns of our time series are not exactly normally distributed as we have seen in the section titled “Volatility and Standard Deviation”. Therefore, the variance–covariance approach can only give an approximation for the correct VaR. Nevertheless, it is useful because it often is the only technique that is applicable in the required time frame and which can be handled at a reasonable cost.

Further Implementation Methods. Besides the methods described above, there are quite a number of extensions and generalizations, which can be found in the literature. Some focus on the modeling of volatility using methods like exponentially weighted moving averages or generalized autoregressive conditional heteroscedasticity. Others relax the distributional assumptions using, e.g., a student’s t

distribution or normal mixtures. An overview on these methods can be found, e.g., in [8].

VaR and CVaR

For a better understanding of risk measures it is helpful to discuss the relations between the different approaches, e.g., between VaR and shortfall probability. While the VaR determines the loss value for a given probability, the shortfall probability gives the probability for a given loss. In case of a continuous distribution function there is an inverse relation as follows:

$$SP(R, \text{VaR}_R(\alpha)) = \alpha \quad (17)$$

Another very strong relationship exists between the expected shortfall and the concept of CVaR (*see Risk Measures and Economic Capital for (Re-)insurers*). The CVaR determines the expected loss under the condition of falling below the VaR. It is defined by

$$\text{CVaR}(\alpha) = -E[R | R \leq -\text{VaR}_R(\alpha)] \cdot P \quad (18)$$

Hence, according to equation (4),

$$\text{CVaR}(\alpha) = ES(R, -\text{VaR}_R(\alpha)) \cdot P \geq \text{VaR}(\alpha) \quad (19)$$

in case of a continuous distribution function.

Coherent Measures of Risk

As we have seen in the previous chapters, there is no one-and-only risk measure for investment decisions, but there exist many different approaches that can be useful for different situations and markets. We thus should answer the question, which characteristics a good risk measure should have. A list of such characteristics was published by Artzner *et al.* in 1999 who called it the four axioms for a coherent risk measure [9, 10].

The Axioms of Coherence

Let X and Y be two random variables and Δt a given time horizon. X and Y are assumed to indicate positive cash flows, so a higher value is better than a lower. Then, ρ is a coherent risk measure if the following four axioms hold (*see Imprecise Reliability*).

Axiom 1 (Translation Invariance) For every real number a we have

$$\rho(X + a) = \rho(X) - a \quad (20)$$

This axiom is necessary for the interpretation of ρ as risk capital. By adding a deterministic quantity a to the risky position, we reduce the required capital reserve by the same amount.

Axiom 2 (Subadditivity)

$$\rho(X + Y) \leq \rho(X) + \rho(Y) \quad (21)$$

The subadditivity reflects the idea of diversification. If we take several risks, the portfolio risk is smaller or equal than the sum of all partial risks.

Axiom 3 (Positive Homogeneity) For every $\lambda > 0$ we have

$$\rho(\lambda \cdot R) = \lambda \cdot \rho(X) \quad (22)$$

There is no netting or diversification if we change the intensity of a risky business. For example, if we buy two shares of a company, the risk of a decreasing stock price will be twice as high as with only one share. Note that subadditivity and positive homogeneity imply that the risk measure ρ is convex.

Axiom 4 (Monotonicity) If $X \leq Y$ for every possible state of nature then we have

$$\rho(X) \geq \rho(Y) \quad (23)$$

If one business unit has a better outcome than another in every possible case, then obviously this business should have a better risk indicator and therefore needs less capital reserves to compensate the risk.

Review of the Presented Measures of Risk

If we check the risk measures described in the sections titled “Traditional Risk Measures” and “Value at Risk” for coherence we can easily see that variance already fails the translation invariance because of $\text{Var}[X + a] = \text{Var}[X]$. Furthermore, VaR fulfils all axioms except subadditivity (see **Insurance Pricing/Nonlife; Premium Calculation and Insurance Pricing; Behavioral Decision Studies**). For an example see, e.g., Zagst [11, p. 257]. It can also be shown that the SP is not coherent.

However, as is shown in Acerbi and Tasche [12], CVaR is a coherent risk measure for continuous distributions.

Summary

Every company needs realistic but challenging targets to survive in competition. Having targets means taking the risk to fail them. Hence, doing successful business requires taking the right risks and controlling them properly. Therefore, we need an appropriate risk measure to quantify the risk and to compare different decision alternatives. All risk measures derive from mathematical stochastics with its basic concepts – mean, variance, skewness, and kurtosis – which we use to describe the probability distributions for future returns. With the VaR, we can determine the possible loss that will not be exceeded with a given probability and determine the required risk capital. This measure is most commonly used in practice. The implemented methods of calculation mainly depend on the availability and quality of the empirical information. The newer concept of CVaR, which is strongly related to the expected shortfall, is a coherent risk measure that is advantageous in the case of returns that are not normally distributed. All discussed concepts provide a toolbox that can be used for quantifying almost every possible risk. However, every measure has specific requirements and assumptions and therefore it is important to use the right risk measure for the specific application.

CHRISTIAN SCHMITT AND RUDI ZAGST

Value Function

A value function rank orders a set of objects (alternatives) X . For a finite X , the following two conditions for any $x', x'', x''' \in X$ guarantee the existence of a value function.

1. Completeness: $x' \succsim x''$ or $x'' \succsim x'$.
2. Transitivity: if $x' \succsim x''$ and $x'' \succsim x'''$, then $x' \succsim x'''$.

The first condition requires that a decision maker must be able to compare any two objects and not declare “I do not know.” Aumann [1] relaxes this condition of comparability. The second condition requires that preference including indifference be transitive. Fishburn [2] argues that the transitivity of indifference may not hold.

The above two conditions are necessary and sufficient for a numerical representation of preference $\succsim$; that is, a function $v : X \rightarrow R$ such that for all $x', x'' \in X$, $x' \succsim x''$ if and only if $v(x') \geq v(x'')$.

The function v is commonly called an *ordinal utility function*. We use the term *value function* to clearly distinguish it from the utility function that is defined over the set of lotteries (choice under uncertainty).

Since the value function merely rank orders (including indifference) the objects in X , it is unique up to a monotone increasing transformation; that is, another value function constructed by a monotone increasing transformation of v will also provide the same rank ordering of objects in X .

In many real-world applications, the objects in X are multidimensional. Examples include consumer decisions, facilities location, new product introduction, and investment decisions. Thus $X = X_1 \times X_2 \times \dots \times X_n$, where X_i is the set of outcomes for criterion i . For a new product decision, cost performance, reliability, and time to market entry may be criteria relevant to ranking alternatives. In these relatively complex cases, additional conditions are needed to simplify the form of the value function. The most common form of the value function is additive:

$$v(x_1, x_2, \dots, x_n) = \sum_{i=1}^n v_i(x_i) \quad (1)$$

Krantz *et al.* [3] provide preference conditions that permit decomposition of the multidimensional value

function into the additive form. A key condition for the additive form is preference independence. Simply stated, preference independence implies that the trade-offs between any pair of criteria are unaffected by the fixed levels of the remaining criteria. Thus, the indifference curves for any pair of criteria do not change if the fixed levels of the remaining $(n - 2)$ criteria are changed.

The value function described above provides an ordinal ranking of alternatives or objects in X . We may wish to order the differences in the strength of preference between pairs of alternatives (see [4]). We shall use the term *measurable value function* for a function that permits ordering of preference differences between alternatives. For axiomatic systems that imply the existence of a measurable value function, see [3] and [5].

Dyer and Sarin [6] provide axioms for both additive and multiplicative measurable value functions. The key condition for an additive measurable value function is difference independence. Simply stated difference independence requires that the preference difference between two alternatives that differ only on one criterion does not depend on the common values of the remaining $(n - 1)$ criteria. An interesting result is that, along with some technical conditions, difference independence for any one criterion along with preference independence discussed earlier for all pairs of criteria implies that the additive value function is also measurable.

A value function is elicited from a decision maker's preferences and therefore reflects decision utility. Another concept that is both classical [7] and modern [8] is experienced utility, which reflects pain and pleasure associated with an experience. The distinction between a value function derived from preference and experienced utility is important for both research and application.

Another important extension of a value function is that the carrier of value is gain and loss from a reference point and not the absolute level [9]. In the area of well-being research, an implication of the reference dependence of a value function is that more money may not necessarily buy more happiness. This is because the reference point increases as wealth increases leaving the net value derived from money unchanged. The applications of value function are described in [10].

RAKESH K. SARIN

Volatility Modeling

Financial asset returns are generally highly unpredictable over shorter horizons such as a day or a month. Put differently – the return standard deviation, or the *volatility*, is much larger than the mean expected return in the short run. Moreover, this extreme short-term risk is fundamental in finance theory as it precludes the existence of simple arbitrage trading strategies (*see Statistical Arbitrage*). So theory asserts that we should expect the price process to be fairly volatile. This is embedded in standard asset pricing theory *via* the requirement that the return process constitutes a so-called semimartingale.

Given the dominance of the variance in the distribution of the returns, at least locally, it is natural that much effort has been exerted in measuring and modeling volatility. In particular, research over the last couple of decades has established that return volatilities across all major asset classes are *time varying* and possess highly *persistent* dynamic components. As such, the volatility is to some degree predictable. This also has direct implications for a range of broader issues, including asset and derivatives pricing, portfolio choice, and risk management.

Although there are alternative ways in which to forecast volatility, the focus of this entry is exclusively on the time series modeling of volatility on the basis of observed market prices. This is also the most universally applicable approach as it merely requires historical price data. To set the stage, we formally define the return variance and standard deviation. We assume, as is commonplace, that the return process is sufficient regular (covariance stationary) that these quantities are well defined. For concreteness, we concentrate initially on a single financial return series. We define the (continuously compounded) return between time t and $t + 1$ as follows,

$$\begin{aligned} r_{t+1} &= \log(P_{t+1}) - \log(P_t) \\ &= p_{t+1} - p_t, \quad t = 1, 2, \dots, T \end{aligned} \quad (1)$$

There are $T + 1$ separate price observations available, resulting in T returns defined through the corresponding log-price differentials. Denoting the (unconditional) expectation of any random variable, say X , by $E[X]$, we can write the (unconditional

or average expected) return standard deviation and variance as, respectively,

$$\sigma = \sqrt{E[(r_t - E[r_t])^2]} \quad (2)$$

and

$$\sigma^2 = E[(r_t - E[r_t])^2] \quad (3)$$

The mean, standard deviation, and variance may be estimated consistently by the corresponding sample moments,

$$\begin{aligned} \hat{\mu} &= \frac{1}{T} \sum_{t=1}^T r_t; \\ \hat{\sigma} &= \sqrt{\frac{1}{T} \sum_{t=1}^T (r_t - \hat{\mu})^2}; \\ \hat{\sigma}^2 &= \frac{1}{T} \sum_{t=1}^T (r_t - \hat{\mu})^2 \end{aligned} \quad (4)$$

This refers, of course, only to the long-run values of these moments. The evidence of persistent and time-varying volatility dynamics implies that the return variation is not constant but fluctuates in a partially predictable manner. That is, if we consider the volatility at time t taking into account the recent return fluctuations and all other relevant information, we should instead focus on the *conditional* volatility and variance given as,

$$\sigma_t = \sqrt{E_{t-1}[(r_t - E_{t-1}[r_t])^2]} \quad (5)$$

and

$$\sigma_t^2 = E_{t-1}[(r_t - E_{t-1}[r_t])^2] \quad (6)$$

where $E_{t-1}[X]$ denotes the expected value of X given all information at time $t - 1$.

The subject of volatility modeling is now readily defined. It is dedicated to the generation of sequential forecasts of the conditional volatility, σ_t or σ_t^2 , in real time as new information emerges and asset volatility evolves. Moreover, for short horizons it is typically safe to ignore the (conditional) mean altogether or, for slightly longer horizons, treat it as a constant, μ , because of the semimartingale property of the return series.

Historically Filtered Volatility Estimates and Forecasts

The simplest possible approach to volatility estimation is to exploit the strong persistence in the series and use recent squared returns as an indicator of the current volatility level. This *ad hoc* method is often labeled *historical volatility*. If daily returns are available, the current volatility is typically estimated through a backward looking window of 1–3 months. If the window contains K daily squared returns, the corresponding volatility and variance estimates are,

$$\hat{\sigma}_t = \sqrt{\frac{1}{K} \sum_{j=1}^K r_{t-j}^2}; \quad \hat{\sigma}_t^2 = \frac{1}{K} \sum_{j=1}^K r_{t-j}^2 \quad (7)$$

More generally, however, one may want to estimate volatility through a weighted average of past squared returns allowing for more weight to be assigned to the more recent observations. In addition, this readily avoids the choice of an arbitrary cutoff associated with the selection of a window length. In this case, the general representation of the variance estimator takes the form,

$$\begin{aligned} \hat{\sigma}_t^2 &= \sum_{j=1}^{\infty} w_j r_{t-j}^2; \\ \sum_{j=1}^{\infty} w_j &= 1; \quad w_j \geq 0, \forall j \geq 1 \end{aligned} \quad (8)$$

The historical volatility (variance) estimator is obtained for $w_j = 1/K$ for $1 \leq j \leq K$ and $w_j = 0$ for $j > K$. A more widespread approach is the so-called *exponential smoothing*. This is achieved by letting $w_j = (1 - \lambda)\lambda^{j-1}$ for all $j \geq 1$, and $0 < \lambda < 1$. It produces a sequential updating equation,

$$\begin{aligned} \hat{\sigma}_t^2 &= (1 - \lambda) \sum_{j=1}^{\infty} \lambda^{j-1} r_{t-j}^2 \\ &= \lambda r_{t-1}^2 + (1 - \lambda) \hat{\sigma}_{t-1}^2 \end{aligned} \quad (9)$$

Since only a finite number of past observations are available, there is a need to complement the formula with an initial condition but the impact of this initial condition wears off quite quickly and does not typically pose a practical problem.

A prominent example of exponential smoothing is Risk Metrics (RM) which applies the method for large sets of conditional asset volatilities and, with minor modifications, conditional covariances. RM does not estimate λ but fixes it uniformly across all assets at 0.06. The advantage is robust and sensible measures that are unaffected by idiosyncratic events or outliers. Avoiding the latter is of primary concern for an automated computational approach, which serves to support portfolio choice applications. On the other hand, there is inevitably a degree of specification error present when using a fixed representation across all assets. Moreover, the approach has some troubling and counterfactual implications, mainly concerning longer-term volatility forecasts. If the return residuals are symmetric, one may iterate the conditional one-step-ahead forecasts forward to generate multi-period forecasts. For RM, the k -period-ahead conditional forecast is, with the convention that $\text{Var}_{t-1}[X]$ denotes the conditional variance of X given all information at time $t - 1$,

$$\begin{aligned} \text{Var}_{t-1}(r_{t+k-1} + r_{t+k-2} + \cdots + r_t) &\equiv \sigma_{t:t+k-1|t-1}^2 \\ &= k\sigma_t^2 \end{aligned} \quad (10)$$

Hence, RM implies linear scaling of the variance forecasts, so that the term *structure of volatility* is flat. If current volatility is low the forecasts project this low state into the future without any adjustments reflecting mean reversion toward a long-run level. Likewise, RM will mechanically translate high current volatility into equally high forecasts for the indefinite future. This is clearly counterfactual as the volatility process appears stationary and displays distinct mean reversion at medium and longer horizons. Another weakness of the RM procedure is the absence of a formal metric for assessing model and forecast fit.

GARCH Volatility Modeling

A rigorous approach to volatility estimation, related to the above filtering techniques, is given by the generalized autoregressive conditional heteroskedasticity (GARCH) model of Bollerslev [1], with GARCH(1,1) being particularly successful and popular. It is a parametric procedure relying on statistical inference for model estimation and forecasting. As such, it represents a full-blown model of the conditional return distribution and not just of the second

moments. Hence, it is necessary to introduce the assumptions invoked on the return generating process explicitly. It is stipulated to take the following general form,

$$\begin{aligned} r_t &= \mu_t + \sigma_t z_t; \quad z_t \sim i.i.d.; \\ E(z_t) &= 0; \quad \text{Var}(z_t) = 1 \end{aligned} \quad (11)$$

The specification of the conditional mean is not critical for practical inference regarding the volatility so we simply fix it at zero, but complex mean dynamics can readily be incorporated into the models below. For now, we postpone the discussion of the distributional assumption on the standardized innovation, z_t , but for concreteness one may assume it to be normal.

The only remaining feature of the return generating process is the evolution of the conditional variance. The symmetric GARCH(1,1) model stipulates that,

$$\sigma_t^2 = \omega + \alpha r_{t-1}^2 + \beta \sigma_{t-1}^2 \quad (12)$$

where the parameters ω , α , and β all are assumed strictly positive and we again require that an initial condition for the conditional variance at $t = 0$ is provided. One may extend the model by including higher-order lags in either squared returns or the conditional variance, but we focus on GARCH(1,1) for brevity. Repeated substitution in equation (9) readily yields, for $0 < \beta < 1$,

$$\sigma_t^2 = \frac{\omega}{1 - \beta} + \alpha \sum_{j=1}^{\infty} \beta^{j-1} r_{t-j}^2 \quad (13)$$

so, apart from a constant, current volatility is an exponentially weighted moving average of past squared returns. If, in addition, as is almost invariably true, $0 < \alpha + \beta < 1$, then the variance process is covariance stationary with unconditional variance σ^2 . We have,

$$\begin{aligned} \sigma_t^2 &= \sigma^2 + (\alpha + \beta)(\sigma_{t-1}^2 - \sigma^2) \\ &\quad + \alpha \sigma_{t-1}^2 (z_{t-1}^2 - 1) \end{aligned} \quad (14)$$

The last term in this representation has mean zero and is serially uncorrelated so it constitutes a genuine volatility innovation. Hence, this is reminiscent of an AR(1) model for the conditional variance with heteroskedastic errors. The size of $\alpha + \beta$ is a critical determinant of the persistence of the volatility

process which constantly drifts toward σ^2 . Typical values for $\alpha + \beta$ with daily data fall in the interval $[0.92, 0.995]$. This corresponds to a half-life of volatility shocks ranging from about 1 week to 6 months. Moreover, note that α governs the volatility of volatility. Hence, a variety of distinct features of the return-volatility process may be accommodated by different parameter constellations within the basic GARCH model. If $\alpha + \beta \geq 1$, the volatility process is sufficiently ill-behaved and the return distribution sufficiently fat tailed that the second return moment no longer exists. For a range of values beyond unity, the volatility process does remain strictly stationary, but for even higher values of $\alpha + \beta$ the process diverges, indicating that the latter scenario is empirically uninteresting.

As mentioned, one advantage of GARCH is that the implied dynamics secure reversion in volatility to a long-run value, enabling interesting and realistic forecasts. Specifically, the GARCH(1,1) forecast for k steps ahead is,

$$\sigma_{t+k|t}^2 = \sigma^2 + (\alpha + \beta)^{k-1} (\sigma_{t+1}^2 - \sigma^2) \quad (15)$$

Since the daily returns are assumed serially uncorrelated, the variance of the k -day cumulative returns, which provide the basic input to the calculation of the volatility term structure, becomes,

$$\begin{aligned} \sigma_{t:t+k|t}^2 &= k \cdot \sigma^2 + (\sigma_{t+1}^2 - \sigma^2) \\ &\quad \times (1 - (\alpha + \beta)^k)(1 - \alpha - \beta)^{-1} \end{aligned} \quad (16)$$

It is evident from equation (15) that volatility shocks have a persistent effect on the forecasts but the effect decays at a geometric rate governed by $\alpha + \beta$. This contrasts sharply with the RM approach. In fact, RM style exponential smoothing is optimal only if the squared returns follow a “random walk plus noise” model, in which case the minimum mean squared error (MSE) forecast at any horizon is simply the current smoothed value. The evidence blatantly contradicts the random walk scenario, implying that the flat forecast function associated with the RM smoothing is unrealistic and undesirable for volatility modeling and forecasting purposes.

The GARCH(1,1) volatility measurement has other advantages. First, the GARCH parameters, and hence the associated volatility estimates, are obtained using statistical methods that facilitate rigorous inference, thus avoiding *ad hoc* selection of

parameters. Typically, one estimates the GARCH parameter vector $\theta = (\omega, \alpha, \beta)$ by maximizing the log-likelihood function,

$$\log L(\theta; r_T, \dots, r_1) \propto - \sum_{t=1}^T [\log \sigma_t^2(\theta) - \sigma_t^{-2}(\theta) r_t^2] \quad (17)$$

This implicitly assumes that the standardized return innovations are normally distributed, but this is largely a matter of convenience. Even if the conditional return distribution is nonnormal, the associated quasi-maximum likelihood estimates (QMLE) of the parameters remain consistent and asymptotically normal under weak conditions. The optimization of the log-likelihood must be done numerically, but GARCH models are parsimonious and the appropriate estimation procedures have been included in many commercially available software packages.

Second, the dynamics associated with GARCH (1,1) afford intuitive interpretations that readily are generalized to accommodate further realistic features. Without providing details, we mention a few important extensions. One, an asymmetric return-volatility relation may be induced through a direct dependence of the volatility dynamics on the sign of the return innovation as in, e.g., the exponential generalized autoregressive conditional heteroskedasticity (EGARCH) model of Nelson [2]. Two, one may incorporate so-called long memory features in the volatility process by having multiple GARCH(1,1) type components in the model, as illustrated by Engle and Lee [3], or directly through a fractionally integrated EGARCH model, as considered by Baillie *et al.* [4]. In either case, volatility shocks will then eventually die out at a slower (approximate) hyperbolic rate than the geometric rate implied by a standard GARCH model. Three, one may allow for fat tails and asymmetries in the standardized return innovation through alternative distributional assumptions. Typical examples are the Student t distribution and the generalized error distribution (GED) as well as extensions thereof. Four, it is feasible to generalize the approach to multivariate systems and model the conditional variance-covariance matrix but parameters proliferate so it is critical to develop parsimonious representations for higher dimensional systems. A variety of approaches has been developed

with the dynamic conditional correlation (DCC) model of Engle [5] and Tse and Tsui [6] being the most tractable and popular. Finally, one may introduce additional explanatory (macroeconomic and financial) variables into the volatility equation and one may even accommodate latent regime shifts through clever parameterizations as in Gray [7]. For surveys providing more details on these issues, see, e.g., Andersen, Bollerslev, Christoffersen, and Diebold (ABCD) [8, 9] on volatility forecasting and risk management, respectively.

Stochastic Volatility Models

GARCH models are examples of stochastic volatility (SV) models. However, GARCH models imply, for given model parameters, that volatility is conditionally deterministic over the next period given the history of returns. Genuine SV models allow volatility for period t to be stochastic, even conditional on all information through period $t - 1$. This is more in line with the continuous-time paradigm of theoretical finance where volatility typically is driven, at least in part, by its own process separate from the return innovations. Moreover, it is natural to associate SV innovations to other concurrent market activity variables, such as trading volume, information flow or bid-ask spreads, see, e.g., Andersen [10]. A generic discrete-time SV model, imposing the mean zero constraint, may take the following form,

$$\begin{aligned} r_t &= \sigma_t z_t; \quad z_t \sim i.i.d. \ N(0, 1); \\ \sigma_t &= h(\sigma_{t-1}, r_{t-1}) + \eta_t; \\ \eta_t &\sim i.i.d. \ (0, \sigma_\eta^2) \end{aligned} \quad (18)$$

This is a generalization of the GARCH return equation (11). The decomposition of the return process into a standardized innovation, z_t , and a volatility process, σ_t , is as before. However, the volatility process is not only a function, $h(\cdot, \cdot)$, of past volatility and returns but also subject to a contemporaneous shock, η_t . The latter feature renders volatility latent or unobserved even conditional on all information through time $t - 1$. SV models are furthermore compatible with the *mixture of distributions hypothesis* (MDH) popularized by Clark [11]. In this theory, the return innovation is conditionally Gaussian, but with a variance which is governed by a separate stochastic process. As such, the full return distribution is a

mixture of the standard normal innovation and the associated variance process. This type of mixture process can rationalize the conditional fat-tailed innovations invariably found in return series. Besides this basic feature, SV models possess a great deal of flexibility through alternative specifications of the h function governing the volatility dynamics and inclusion of additional lags and/or explanatory variables.

Because the SV models imply a latent volatility process, they can be harder to estimate and analyze than GARCH models even if dramatic progress has been made recently in terms of estimation and inference *via* different simulation based techniques. Nonetheless, the basic features of the estimated models and the ability to empirically fit the properties of the volatility processes are not very different across the two model classes. Hence, we do not explore these models further and instead refer to existing surveys such as Andersen *et al.* (ABCD) [9] or Shephard [12].

Realized Volatility Modeling

The increased availability of high-frequency intraday data has spurred a novel approach to volatility measurement and modeling, in some sense taking us full circle and bringing back into focus a concept that refines the notion of historical volatility discussed in the introduction. The motivation is that if volatility evolves continuously then a rich history of tick-by-tick transaction prices and quotes should provide an opportunity to measure the process with good precision, even over relatively short intervals, as argued in Andersen and Bollerslev [13, 14] by extension of the ideas of Merton [15] and also independently developed by Zhou [16]. Here, we follow Andersen *et al.* [17] (henceforth ABDL) and define the *realized variation* (informally also denoted *realized volatility* (RV)), on day t using returns constructed at the Δ intraday frequency as

$$RV_t \equiv \sum_{j=1}^{1/\Delta} r_{t-1+j\Delta, \Delta}^2 \quad (19)$$

where $1/\Delta$ is, for example, 144 for 10-min returns in 24-h markets or 78 for 5-min returns over a 6.5-h trading day. In theory, letting Δ go to zero, which implies continuous sampling, RV will approach

the true *integrated variation*, IV , of the underlying return process under weak assumptions related to the absence of arbitrage. Hence, we may obtain direct and observable indicators of realized return variation for each day in our sample, independently of any specific model. This simplifies matters greatly as we avoid issues such as model adequacy and inference regarding latent volatility processes.

A simple scenario illustrates how the RV relates to actual return volatility. Assume the true (mean zero) price process evolves according to a semimartingale in continuous time and does not display discontinuities (or jumps), and that the volatility process evolves independently of the price process. Then the return over period t , conditional on the full path of the volatility process over the period, is normally distributed and characterized through the simple summary statistics, the integrated variance IV_t ,

$$r_t | \sigma_{[t-1, t]} \sim N(0, IV_t),$$

$$\text{where} \quad IV_t = \int_{t-1}^t \sigma_u^2 du \quad (20)$$

This result is directly in line with the discrete-time return distribution in SV models as stated in equation (18). The return is conditional Gaussian with a variance governed by the (stochastic) realization of the integrated variance for period t . Hence, the RV approach extends the SV models naturally to the continuous-time setting. The return distribution is a mixture of the standard normal and the distribution of the (integrated) variance, where the IV_t measure is genuinely random and thus not fully predictable from information available at time $t-1$. It is also worth noting that the IV concept occupies a central role in the theory of option pricing under SV, see Hull and White [18]. Of course, we never observe IV_t perfectly, even *ex post*, but only estimate it, e.g., *via* the corresponding cumulative sum of squared intraday returns, RV_t . The discretization error incurred because RV is constructed from a finite sample of intraday returns rather than a continuous price record may be assessed using the asymptotic theory developed by Barndorff *et al.* [19].

If the assumptions above are violated because of price jumps or correlation between price and volatility innovations, the return process will display more complex distributional characteristics (*see Lévy Processes in Asset Pricing*). Some of these features are

subject of current work in the literature. For example, tests for the presence of jumps are available using alternative cumulative return variation measures. One may thus decompose RV into contributions from jumps *vis-a-vis* the continuous part of the sample path. This has proven useful for volatility forecasting as the persistence of the volatility process predominantly is driven by the continuous piece of the return distribution. As a consequence, filtering out the jump component helps improve forecast accuracy, as documented in Andersen *et al.* [20], henceforth ABD.

Another complication is the presence of market microstructure features and/or noise that tend to obscure the properties of the true return process at the very highest sampling frequencies. This includes issues such as bid-ask bounce, the existence of a price grid, and the lack of a truly continuous sampling and trading/quoting record. These complications suggest that it is better to compute RV from somewhat lower frequencies such as 1- to 10-min intervals rather than tick-by-tick data or including explicit corrections for the presence of noise. A nice overview of this literature is given by Hansen and Lunde [21]. In either case, the measure of realized variation includes the true underlying return variation plus an error term, which is in general, serially uncorrelated. A related issue is the presence of a strong intraday volatility pattern which induces an artificial dependence structure in RV measures spanning less than a full trading day. A simple and robust response is to only construct RV measures for periods that comprise (a multiple of) one trading day, and this is now common practice in the literature.

The availability of actual return-volatility observations with only an uncorrelated measurement error disguising the true underlying realizations provides the impetus for direct time series modeling of volatility. For example, ABDL pursue a standard ARMA style model, only extended to allow for long memory features, for the logarithmic RV of foreign exchange rates. The associated fit for the future return volatility is found to dominate that of traditional volatility GARCH models based on daily data. An even simpler and quite effective approach is to pursue a simple component based regression model. The long memory features of the volatility process is accommodated well in this fashion. Specifically, using the so-called heterogeneous autoregressive (HAR) model of Corsi [22], ABD propose a simple HAR-RV specification

where $R_{t-h:t-1}$ denotes the average daily RV over the interval $[t-h, t-1]$,

$$RV_t = c_0 + c_d RV_{t-1} + c_w RV_{t-5:t-1} + c_m RV_{t-22:t-1} + u_t \quad (21)$$

The regression coefficients may be estimated directly by ordinary least squares (OLS) from historical data, and forecast then generated for future volatility in a straightforward manner. The inclusion of the past daily, weekly, and monthly RV is sufficient to provide a reasonable approximation to the slow hyperbolic delay in the (realized) volatility persistence documented in numerous studies.

Obviously, the simple model in equation (21) may be refined and extended in many directions and much current work is dedicated to doing so. Besides the jump filtering mentioned previously, examples include incorporation of overnight and holiday volatility indicators, the treatment of scheduled economic news announcements, and the addition of alternative explanatory variables such as volatility forecasts implied by option prices or volatility swap contracts (*see Volatility Smile*). Finally, it is of interest to document the economic, as opposed to statistical, value of RV forecasts for practical applications. An initial illustration is given by Fleming *et al.* [23].

In principle, it is also straightforward to extend the realized variation concept to encompass realized covariation. This is achieved by cumulating concurrent high-frequency return cross products rather than squared returns. The ability to provide direct measures of time-varying return covariances are of direct interest for factor-based asset pricing models, including the capital asset pricing model (CAPM) and the arbitrage pricing theory. Promising and intriguing results have been obtained for liquid assets, see, e.g., Andersen *et al.* [24] documenting systematic shifts in the exposure of value *versus* growth portfolios over the business cycle. Unfortunately, the covariance measures are even more susceptible to market microstructure distortions than the basic RV measure. Consequently, this issue is subject to intense research efforts, but nobody has yet proposed a method that is both tractable and robust. However, this work is still in its infancy and much progress will surely occur over the next few years.

Finally, there is the issue of how to apply RV-like approaches if markets are not quite as liquid

as the major financial markets. One possibility is to lower the sampling frequency and measure volatility over longer time intervals, e.g., weekly or monthly rather than daily. Another approach uses more robust volatility indicators such as the high–low price range to deal with the worse signal-to-noise ratio in less liquid markets, see, e.g., Alizadeh *et al.* [25]. A particularly compelling piece detailing the links between RV and intraday range–based volatility measures is given by Dobrev [26].

Conclusion

In summary, volatility modeling continues to pose interesting and important practical challenges that motivate the development of new econometric theory and implementation techniques. Moreover, the current frontier research dealing with volatility and correlation measurement via intraday data is finding immediate applications in trading firms and investment banks. This direct interaction between theory and practice is sure to invigorate further research in the coming years.

Volatility Smile

The Black and Scholes [1] model lays the foundation to the modern option pricing theory. It prescribes the option price as a function of the volatility of the underlying asset and some other pertinent and observable variables. One important assumption of the Black–Scholes model is that the price of the underlying asset follows a geometric Brownian motion with constant drift and volatility; that is,

$$\frac{dS_t}{S_t} = \mu dt + \sigma dW_t^P \quad (1)$$

where W_t^P is the standard Brownian motion with respect to the physical probability measure P . By employing a continuous hedging argument, they then derived the following European call option pricing formula:

$$C_t = S_t N(d_t) - X e^{-r(T-t)} N\left(d_t - \sigma \sqrt{T-t}\right) \quad (2)$$

where $d_t = \frac{\ln(S_t/X) + (r + 0.5\sigma^2)(T-t)}{\sigma \sqrt{T-t}}$, $N(\cdot)$ is the standard normal distribution function, X is the strike price, $T - t$ is the remaining maturity, and r is the risk-free interest rate (see **Numerical Schemes for Stochastic Differential Equation Models**).

Subsequently, several researchers [2–4] proposed a powerful way of viewing option pricing as a risk-neutral valuation problem (see **Risk-Neutral Pricing: Importance and Relevance**). After transforming the probability measure P to Q , one can price options by acting as if one were risk-neutral and employing the following price process with an altered drift:

$$\frac{dS_t}{S_t} = r dt + \sigma dW_t^Q \quad (3)$$

where W_t^Q is the standard Brownian motion with respect to the risk-neutral probability measure Q . This approach yields the same Black–Scholes option pricing formula. In fact, the idea is applicable to any continuous-time continuous sample path semimartingale so that the discounted asset value becomes a martingale under measure Q .

Empirically, the Black–Scholes model has been shown to have rather unsatisfactory performance. Its deficiency is most notable when the Black–Scholes implied volatility is related to strike price and

maturity. For a European option, one can easily compute the implied volatility by using the Black–Scholes formula to back out a unique volatility that equates the formula value to the market price of the option. Since the implied volatility is meant for the underlying asset, options on the same underlying should not have their implied volatilities exhibiting any systematic pattern in relation to strike price or maturity. The empirical evidence extensively reported in the literature, however, suggests otherwise. Figure 1 reports the implied volatilities of the S&P 500 index options (out-of-the-money calls and puts) on April 7, 2006 corresponding to different maturities and strike prices. The patterns in Figure 1 are typical of index options. It is evident that the implied volatility corresponding to a maturity is generally downward sloping when the strike price is less than the S&P 500 index value, i.e., out-of-the-money puts (corresponding to in-the-money calls by the put-call parity). When the strike price goes beyond the index value, it begins to slope upward. The implied volatility curve in relation to the strike price is commonly referred to as the volatility smile (sometimes volatility smirk). If we fix the attention at a strike price and examine them in terms of maturity, it is evident that the implied volatility will be mostly decreasing in maturity except for the strike price at around the index value. Such kind of phenomenon is known as the term *structure of implied volatilities*.

Understanding what causes volatility smile is crucial to the financial economists' search for a better option pricing model. At the practical level, devising a workable way of incorporating volatility smile is also vital to industry practitioners in their daily tasks of pricing options and risk manage their trading books. Researchers and practitioners have sought to address volatility smile along two paths. The first path is to incorporate volatility smile through nonparametric techniques, such as implied-tree models, kernel regressions, neural networks, and entropy principle, without actually focusing on the cause of volatility smile. Naturally, such solutions without subjecting to economic constraints are likely to work well for the tasks that are in essence interpolation, say for example, pricing a European option with a different strike price. Among them, the implied-tree models are different and deserve further comments later.

The second path is through parametric approaches such as stochastic volatility models, jump-diffusion

Figure 1 Implied volatilities of the S&P 500 index options (out-of-the-money calls and puts) on April 7, 2006 corresponding to different maturities and strike prices

models (see **Lévy Processes in Asset Pricing**) and generalized autoregressive conditional heteroskedasticity (GARCH) models (see **Statistical Arbitrage**). These are pricing theories comparable to the Black–Scholes model in the sense that they first postulate an asset price dynamic and then derive the option pricing model through an economic argument. These models can, in principle, price any option – European, American, and exotic. Although the economic constraints may lead them to perform not as well for specific interpolation tasks, they have a much wider applicability for a whole spectrum of pricing and risk-management tasks. In this article, we will cover both modeling approaches and offer a brief description and discussion on specific methods in both categories. In particular, we will demonstrate by examples the use of the kernel regression method and the GARCH option pricing model.

Nonparametric Methods

Nonparametric methods leave specific function forms open and let data speak for themselves. The performance of nonparametric methods will, of course, be better when the assumptions of parametric models are violated. Flexibility inevitably comes at a cost. Nonparametric techniques typically require a large

quantity of data in implementation, which limits their applicability or renders them completely unworkable in some circumstances. Nevertheless, nonparametric techniques offer a valuable set of tools that can be extremely useful for some applications in option pricing and risk management. The well-known nonparametric methods that can handle volatility smile include implied-tree models [5–7], learning networks [8], principle of maximum entropy [9–11], and kernel regressions [12].

In this article, we use kernel regression as an example to demonstrate the use of nonparametric techniques. Kernel regression is a popular tool for figuring out the nonlinear relationship among variables. The main assumption is that the unknown functional form is sufficiently smooth. Kernel regression was first applied to option pricing by Ait-Sahalia and Lo [12]. They assumed that the Black–Scholes’ implied volatility is a smooth function of two contract attributes – moneyness (strike price over asset price) and maturity. However, the functional form is unknown. Ait-Sahalia and Lo [12] employed the Nadaraya–Watson kernel estimator, which in this case is the weighted average of observed implied volatilities for the existing options with the weight depending on how close the target point’s attributes are to those of the existing options. If the distance to an option is large (small), the weight will

be small (large). The kernel function is a two-dimensional Gaussian density with a bandwidth to be determined by the data. (The bandwidth determines how fast the weight declines in relation to the distance).

Since the kernel regression is applied to the implied volatility directly, the Black–Scholes formula is needed to recover the option value corresponding to the implied volatility predicted by the kernel regression. Needless to say, one can also apply the kernel regression directly on option prices. In principle, neither way dominates, but in practice, the choice should depend on the specific application and/or one's preferences in weighting in- and out-of-the-money options; for example, using option prices as opposed to implied volatilities amounts to committing to a different weighting scheme on the regression errors.

The kernel estimator is a smooth function by construction, and can thus be used to interpolate in moneyness and maturity. But the kernel estimator should not be used for extrapolation, because no reference points can be used to anchor the unknown functional relationship beyond the data range. In fact, the quality of Nadaraya–Watson kernel estimator is known to be poor for points within but close to the boundary of the data range. An alternative with a better boundary performance is a local linear kernel regression [13]. Kernel regressions are much more data intensive than implied-tree models, which are a category of nonparametric techniques based on precommitting to a tree structure in fitting the observed option prices. Furthermore, the kernel regression function constructed from one type of options cannot be used to price other types of options, whereas implied-tree models can be. Evidence suggests, however, implied-tree models are too restrictive to match volatility smiles over time without frequent recalibrations. Thus, kernel regressions stand to be a very useful nonparametric tool for option pricing. Now we demonstrate the performance of a kernel regression in matching volatility smiles both in-sample and out-of-the-sample.

In deciding what enter into the kernel function, we note the importance of adding historical volatility as the third attribute. Including historical volatility is important because the asset volatility is known to change over time. Thus, our kernel regression consists of three regressors – moneyness, maturity, and historical volatility. The historical volatility is computed from the 252 daily returns

immediately preceding any given day in the sample. For simplicity, we use the Nadaraya–Watson kernel estimator with a three-dimensional Gaussian kernel function. The bandwidth determines how fast the weight declines. Too small a bandwidth can result in an in-sample overfit, whereas too large a bandwidth can cause over smoothing and large biases. The bandwidth in our demonstration is determined with the standard leave-one-out cross validation.

All strike prices and maturities during the period March 1, 2006 to March 31, 2006 (daily) are included if market prices of options give rise to valid implied volatilities. Option data are taken from option metrics. The root mean squared error of annualized implied volatilities for the sample is 0.0024. Fitting errors (the market annualized implied volatility minus the kernel estimate) are smaller for longer-term options. This is not surprising as Figure 1 indicates that the volatility smile phenomenon is least pronounced for long-term options.

Naturally, one would like to know how the kernel regression function performs out-of-the-sample. For this, we check the performance one week ahead on April 7, 2006. The root mean squared error turns out to be 0.019764, which is about eight times the in-sample error magnitude. This suggests that the in-sample kernel regression has likely been overfitted. One plausible cause is that historical volatility, one of our three regressors, fails to properly reflect market volatility but the kernel regression function has been forced to adapt to the in-sample option data.

Figure 2 plots the out-of-the-sample fitting errors of the kernel regression for the implied volatilities of the S&P 500 index options on April 7, 2006. Fitting errors of short-term options are larger and exhibit a smilelike shape, indicating that kernel regression has not succeeded in removing volatility smile completely.

Parametric Models

Parametric option pricing models begin by postulating a stochastic process for the underlying risk factor(s), typically the underlying asset price. Economic arguments (arbitrage (*see Statistical Arbitrage*) or equilibrium (*see Risk-Neutral Pricing: Importance and Relevance*)) are then employed to develop the functional relationship linking the price of an option to the underlying asset price and the parameters which govern the stochastic process and

Figure 2 Out-of-the-sample fitting errors of the kernel regression for the implied volatilities of the S&P 500 index options (April 7, 2006)

the option contract. The parametric option pricing model can be implemented with first estimating the parameters of the stochastic process using the time series of the underlying asset prices. Alternatively, one can directly apply the functional relationship to calibrate the model to the observed option prices without using the price time series. The former implementation scenario is uniquely available to parametric option pricing models because they offer an explicit link between the risk-neutral and physical price dynamics for the underlying asset. In principle, one can also combine both the underlying asset and option prices to perform a joint estimation of a parametric model.

Benefiting from the model restrictions, implementing parametric option pricing models is less data intensive. In addition, parametric option pricing models can be used to extrapolate for options with strike prices and maturities outside the data range. In principle, these models can also be used to price different types of derivatives, because different pricing functions share the same model parameters.

A parametric pricing model thus provides a complete solution to option pricing. In practice, however, the restrictions placed on the system for deriving the model may be too constraining, and thus render the resulting model a poor performer empirically. The well-known parametric option pricing models are stochastic volatility [14, 15], jump-diffusion [16, 17], and GARCH [18].

We use the GARCH option pricing model to show how a parametric pricing model can be used to deal with volatility smile. Autoregressive conditional heteroskedasticity (ARCH) modeling was pioneered by Engle [19] and its generalized version, known as *GARCH*, has been widely adopted in modeling financial time series with proven success. In a nutshell, the GARCH model treats the volatility as a deterministic function of past innovations. Different GARCH specifications simply employ different deterministic functions in linking the past innovations to the current volatility. The GARCH volatility is not a latent variable because volatility is simply a deterministic transformation of the past innovations. This stands

in sharp contrast to stochastic volatility models and has practical significance for option pricing, because volatility in the stochastic volatility model, being a latent variable, has a nondegenerate distribution which makes model implementation difficult.

The option pricing theory under GARCH was first developed by Duan [18] using an equilibrium argument. Later, Kallsen and Taqqu [20] showed that the same GARCH option pricing model can be obtained by an arbitrage-free argument (*see Statistical Arbitrage*) using a properly constructed continuous-time GARCH process. Estimating the GARCH model using the time series of asset prices is an easy task, and most statistical packages, in fact, have built-in modules for this. Valuing derivatives using the GARCH option pricing model is generally speaking computer intensive. For European options, some approximation formulas are available, however. Empirical studies show that the GARCH option pricing model performs well particularly with the nonlinear asymmetric generalized autoregressive conditional heteroskedasticity (NGARCH) specification of Engle and Ng [21]; see, for example, Christoffersen and Jacobs [22].

We now use the GARCH option pricing model to demonstrate its application to option data. Specifically, the asset price under the physical probability measure P is assumed to follow the NGARCH(1,1) specification of Engle and Ng [21]:

$$\begin{aligned} \ln \frac{S_{t+1}}{S_t} &= r - q + \lambda \sigma_{t+1} - \frac{1}{2} \sigma_{t+1}^2 + \sigma_{t+1} \varepsilon_{t+1}^P \\ \sigma_{t+1}^2 &= \beta_0 + \beta_1 \sigma_t^2 + \beta_2 \sigma_t^2 (\varepsilon_t^P - \theta)^2 \end{aligned} \quad (4)$$

where ε_{t+1}^P is a P -standard normal random variable conditional on the time t information; and q is the continuously compounded dividend yield. A positive value for parameter θ leads to an asymmetric volatility response to the return innovation, an empirical phenomenon commonly known as *leverage effect*.

By the local risk-neutral valuation relationship of Duan [18], the corresponding risk-neutral pricing system becomes

$$\begin{aligned} \ln \frac{S_{t+1}}{S_t} &= r - q - \frac{1}{2} \sigma_{t+1}^2 + \sigma_{t+1} \varepsilon_{t+1}^Q \\ \sigma_{t+1}^2 &= \beta_0 + \beta_1 \sigma_t^2 + \beta_2 \sigma_t^2 (\varepsilon_t^Q - \theta - \lambda)^2 \end{aligned} \quad (5)$$

where $\varepsilon_{t+1}^Q = \varepsilon_{t+1}^P + \lambda$ is a Q -standard normal random variable conditional on the time t information. Because both θ and λ are expected to be positive, this

transformation from measure P to Q increases the volatility persistence, which in turn raises the stationary volatility and causes the cumulative asset return to be more negatively skewed.

There are five parameters in this pricing model: $\beta_0, \beta_1, \beta_2, \theta$, and λ . Maximum-likelihood estimation is performed using the time series of the S&P 500 index values from April 1, 2001 to March 31, 2006. It is well-known in the time series literature that at daily frequency it is hard to estimate the conditional mean parameters (in this case λ) with satisfactory accuracy. Thus the estimates are kept for $\beta_0, \beta_1, \beta_2$, and θ but λ is updated by calibrating the GARCH option pricing model to the option data over the period March 1, 2006 to March 31, 2006, which is the same period used previously in the kernel regression analysis. The calibration is conducted by matching the implied volatility of the GARCH option price to the implied volatility of the market price. The GARCH option prices are computed with 5000 sample path empirical martingale simulation of Duan and Simonato [23]. This two-step procedure yields the following result: $\beta_0 = 5.34 \times 10^{-7}$, $\beta_1 = 0.88863$, $\beta_2 = 0.02599$, $\theta = 1.76056$, and $\lambda = 0.17159$. The root mean squared error of the calibration step is 0.03090, which is much larger than 0.0024, the root mean squared error of the kernel regression on the same data set. Similar to the kernel regression, the fitting errors are larger for short-term options. Moreover, the fitting errors for short-term options continue to exhibit a smilelike shape, indicating that the GARCH option pricing model has not succeeded in removing volatility smile completely.

The fitting result suggests that a better risk-neutral distribution will be the one with heavier tails. The inability of the GARCH option pricing model of Duan [18] may be attributed to its imposition of conditional normality. The GARCH option pricing model with a compound Poisson innovation such as in [24] will likely fit these options better.

When the GARCH option pricing model is applied out-of-the-sample, it produces a fairly stable performance result. The performance one week ahead on April 7, 2006 yields the root mean squared error of 0.05418. This stands in sharp contrast to the kernel regression method, which yields a drastically worse out-of-the-sample performance.

Figure 3 plots the out-of-the-sample fitting errors for three maturity categories. Compared to those of kernel regression, the fitting errors are larger but

Figure 3 Out-of-the-sample fitting errors of the GARCH option pricing model for the implied volatilities of the S&P 500 index options (April 7, 2006)

have similar patterns, i.e., fitting errors of short-term options are larger and exhibit a smilelike shape.

Vulnerability Analysis for Environmental Hazards

What makes people and places vulnerable to environmental hazards and threats? Broadly speaking, vulnerability is the potential for loss or other adverse impacts, or the capacity to suffer harm from an environmental hazard [1, 2]. Hazards, disasters, or extreme events arise from the interaction between human systems and natural systems (natural hazards or natural disasters); but they also can arise from technological failures such as chemical accidents, and from human-induced or willful acts such as terrorism [3]. Vulnerability can be examined at the individual level (for example, the health sciences look at individual people, while the engineering sciences look at the vulnerability of individual buildings or structures). However, hazards vulnerability is most often used to describe the susceptibility of social systems (human communities) or environmental systems (ecosystems) to environmental threats (*see Environmental Health Risk; Environmental Hazard*).

Vulnerability science is in its intellectual infancy and builds on the existing interdisciplinary and integrated traditions of risk, hazards, and disasters research, incorporating both qualitative and quantitative approaches, local to global geography, historic to future temporal domains, and best practices [4]. Spatial social science is critical in advancing vulnerability science through improvements in geospatial data, basic science, and application. It adds technological sophistication and analytical capabilities, especially in the realm of the geospatial and computational sciences, and integrates perspectives from the natural, social, health, and engineering sciences.

Vulnerability analysis seeks to understand the circumstances that place people and localities at risk (their susceptibility), in particular, those circumstances that enhance or reduce the ability of people and places to respond to them (their resilience). For example, some places are simply more vulnerable to hazards than others by virtue of their location (e.g., along coastlines, or along rivers) [5]. In other places, the vulnerability may be a function of the characteristics of people who live there (i.e., the homeless, the poor), where some social groups are more at risk and least able to recover from disasters than others.

Hazard Vulnerability

Physical hazard vulnerability is determined by examining the areal extent of exposure, and the specific characteristics of the potential hazards including magnitude, intensity, frequency, duration, temporal spacing, and rate of onset. For example, to examine the vulnerability of a location to flooding, the likely area of impact must first be determined. The geometry of the impact can be mapped, such as a floodplain (an area prone to flooding). Following this, either historic frequency data or probabilistic data can be applied to the delineated area to measure vulnerability. In this way, a spatial measure of the vulnerability is identified and the resultant product is the map of a 100-year floodplain (or the floodplain that will experience an annual 1% chance flood). Unfortunately, not all types of hazards have quantitative measures for all the characteristics, and in those instances qualitative descriptors are used to describe the events such as strong or weak, fast or slow, small area or large area. The mapping of the hazard zones has a long history [6]. However, the use of more sophisticated geospatial data and technologies such as geographic information systems (GISs) has led to improvements in hazard mapping and vulnerability analyses [7, 8].

Once these areas of exposure are delineated, then they can be used to determine the likely population at risk. The number of people and or structures in harm's way provides one set of measures for understanding vulnerability. Yet, individuals and societies have varying coping capacities, and vulnerability analysis needs to consider the differential capacity that social groups have in the face of disasters.

Social Vulnerability

Social vulnerability is a product of social inequalities. Social vulnerability is a well-developed scientific concept that transcends the expedient descriptors such as race, ethnicity, or poverty [9]. Although it is still not well-understood how each social factor works to produce vulnerability, or necessarily how factors come to work together as amplifiers or attenuators, several broad drivers of social vulnerability have found acceptance within the hazards literature. Generally, these include access to resources and political power; social capital and social networks; beliefs, culture, and customs; building stock and age; frail and

Figure 1 The Social Vulnerability Index (SoVI) for 2000. The cartographic representation of social vulnerability illustrates the extremes in the distribution of the scores. Those counties in black represent the most socially vulnerable places, while the counties in white are the least socially vulnerable. The underlying factors contributing to these patterns are socioeconomic status, age, and the density of the built environment. *Source:* <http://www.cas.sc.edu/geog/hrl/sovi.html> [Reproduced from [14]. © Blackwell Publishing, 2006.]

physically limited individuals; and type and density of infrastructure and lifelines [10–13].

An index of social vulnerability has been generated for US counties, which provides a quantitative assessment of the driving forces [14]. This metric (Social Vulnerability Index or SoVI) permits the identification of regional differences in the relative level of vulnerability across the United States (Figure 1). The SoVI helps to understand the preexisting conditions that contribute to social vulnerability and those circumstances that may influence the ability of the place to respond to and recover from disasters. While initially developed at the county scale for a single time period, SoVI has now been reproduced for various time periods (1960–2000) and for different geographical scales (census tracts) [15].

Policy Perspectives

In many places, it is the combination of social and physical vulnerabilities that potentially undermine a community's ability to respond and recover

from disaster [16, 17]. It is for this reason that vulnerability analyses play an important role in hazards and disaster planning and policy. As part of the US Disaster Mitigation Act of 2000, all state and local governments must develop hazard mitigation plans, and those plans must be based on all hazards vulnerability analyses. Multihazard maps are now part of the public risk and hazard communication effort (www.hazardmaps.gov/atlas.php). The implementation of a conceptually derived place-based vulnerability analysis [7] has led to more science-based hazards assessments at state and local levels. On the international level, there is also considerable interest in vulnerability assessments as part of global efforts to reduce the impacts of disasters [18, 19]. The use of vulnerability analysis in public policies and as the scientific basis for disaster reduction shows great promise. However, the choice of indicators, the availability of place-specific data, and the methodological approaches are still in their infancy, but with continued advancements in vulnerability science these should be overcome in short order [20].

SUSAN L. CUTTER

Warranty Analysis

New products have been appearing on the market at an ever-increasing rate due to the ever-increasing pace of technological innovation. Each generation of products typically incorporates new features and is more complex than the one it replaces. With the increase in complexity and the use of new materials and design methodologies, product reliability becomes an increasingly important issue. One way for the manufacturer to reduce the buyer's risk is to offer a warranty with the sale of the product. In very simple terms, the warranty assures the buyer that the manufacturer will either repair or replace items that do not perform satisfactorily or refund a fraction or the whole of the sale price in the event of product failure. Offering a warranty results in a significant risk to the manufacturer in the form of the expected cost of servicing the warranty. This cost must be assessed very early in the product development stage in order to make decisions with regard to desired product reliability and appropriate product pricing.

This article deals with warranty cost analysis for some simple warranty policies. This involves building models for claims under warranty, taking into account the reliability of the product. The outline of the article is as follows. The section titled "Product Warranty" looks at the basic concept of a warranty and provides a few examples of commonly used consumer warranties. The cost of warranty is impacted by product reliability in an obvious fashion. Some key reliability results needed in assessing this impact are summarized in the section titled "Product Reliability". Probabilistic results used in modeling warranty costs are given in the section titled "Product Reliability" and are applied to the analysis of cost per unit sold and life cycle cost of warranty in the sections titled "Modeling Warranty Cost per Unit Sold" and "Warranty Cost Over Life Cycle", respectively.

Product Warranty

Warranty Concept

A warranty is a contractual agreement between buyer and manufacturer (or seller) that is entered into upon sale of the product or service. The purpose of a

warranty is to establish liability of the manufacturer in the event that an item fails or is unable to perform its intended function when properly used. The warranty (often referred to as the *base warranty*) is an integral part of the sale (a service bundled with the product) and the risk assumed by the manufacturer in offering the warranty is factored into the price. In contrast, extended warranty is a service contract that a buyer might purchase separately to extend the warranty coverage once the base warranty expires.

Warranties are an integral part of nearly all consumer and commercial purchases and also of many government transactions that involve manufactured products. In such transactions, warranties serve a somewhat different purpose for buyer and manufacturer. For a more detailed discussion of the role of warranty from buyer and manufacturer perspectives, see [1]. There are many aspects of warranty and these have been studied by researchers from many different disciplines. A discussion of these can be found in [2].

Classification of Warranties

A taxonomy for warranty classification was first proposed by Blischke and Murthy [3]. Figure 1 is a chart showing the classification scheme. The first criterion for classification is whether or not the manufacturer is required to carry out further product development (for example, to improve product reliability) subsequent to the sale of the product. Policies that do not involve such further product development can be further divided into two groups: the first consisting of policies applicable for single item sales and the second consisting of policies used in the sale of groups of items (called *lot* or *batch sales*).

Policies in the first group can be subdivided into two subgroups based on whether the policy is renewing or nonrenewing. For renewing policies, the warranty period begins anew with each replacement, while for nonrenewing policies the replacement (or repaired) item assumes the remaining warranty time of the item it replaced. A further subdivision comes about in that warranties may be classified as "simple" or "combination". The commonly used consumer warranties featuring free-replacement warranty (FRW) and replacement at pro rata warranties (PRW) (discussed in the next section) are simple policies. A combination policy is a simple policy combined with

Figure 1 Classification of warranties

some additional features or a policy that combines the terms of two or more simple policies. Each of these four groupings can be further subdivided into two subgroups based on whether the policy is one dimensional or two (or higher) dimensional. A one-dimensional policy is one that is most often based on either time or age of the item, but could instead be based on usage. An example is a 1-year warranty on television with the option for buyers to purchase extended warranty coverage. In contrast, a two-dimensional policy is based on time or age as well as usage. An example is an automobile warranty with a time limit of 3 years and a usage limit of 30 000 miles. The warranty expires when one of the limits is exceeded.

Some Simple Warranty Policies

Three simple warranty policies are defined in this section. The cost analysis for each of these is given in later sections.

Policy 1: one-dimensional (1D) nonrenewing free-replacement warranty (FRW)

The manufacturer agrees to repair or provide replacements for failed items free of charge up to a time W from the time of the initial purchase. The warranty expires at time W after purchase.

Typical applications of this warranty are consumer products, ranging from inexpensive items (*see Reliability of Consumer Goods with “Fast Turn Around”*) such as alarm clocks and small radios to relatively expensive repairable items (*see Degradation and Shock Models*) such as automobiles and nonrepairable items such as microchips and other electronic components.

Policy 2: one-dimensional nonrenewing pro rata warranty (PRW)

The manufacturer agrees to refund a fraction of the purchase price if the item fails before time W from the time of the initial purchase. The buyer is not constrained to buy a replacement item.

Under the PRW, the refund given depends on the age of the item at failure. In the most common form of PRW, the refund is determined by the linear relationship $q(x) = [(W - x)/W]P$, where W is the warranty period, x is the age at failure, P is the sale price, and $q(\cdot)$, called the *rebate function*, is the amount of refund. Typically, these policies are offered on relatively inexpensive nonrepairable products such as batteries, tires, ceramics, etc.

Policy 3: two-dimensional (2D) nonrenewing FRW

The manufacturer agrees to repair or provide a replacement for failed items free of charge up to a time W from the time of initial purchase (limit on

time) or up to a usage U (limit on usage), whichever occurs first.

Product Reliability

The modeling of first failures is different from that of subsequent failures. In the latter case, the result depends on whether the failed item is repaired or replaced by a new item.

One-Dimensional Failure Modeling

First Failure. The time to first failure, T , is a random variable that can assume values in the interval $[0, \infty)$, with distribution function

$$F(t) = P(T \leq t), \quad 0 \leq t < \infty \quad (1)$$

The *density function* (if $F(t)$ is differentiable) is given by $f(t) = dF(t)/dt$. The reliability (of the item) is given by the survivor function

$$S(t) = P(T > t) = 1 - P(T \leq t) = 1 - F(t) \quad (2)$$

The failure rate function (or hazard function) (see **Hazard and Hazard Ratio**) $h(t)$ associated with $F(t)$ is defined as

$$h(t) = \frac{f(t)}{1 - F(t)} \quad (3)$$

Subsequent Failures. When a repairable component fails, it can either be repaired or replaced by a new component. In the case of a nonrepairable component, the only option is to replace the failed component by a new item. Since failures occur in an uncertain manner, the number of components needed over a given time interval is a non-negative, integer-valued random variable. The distribution of this variable depends on the failure distribution of the component, the actions (repair or replace) taken after each failure, and, if repaired, the type of repair. The number of failures $N(t)$ over the interval $[0, t)$, starting with a new component at $t = 0$, can be modeled as a *counting process*.

Nonrepairable item. In the case of a nonrepairable component, every failure results in the replacement of the failed component by a new item. If the time to replace a failed component by a new one is

small relative to the mean time to failure (MTTF), then it can be ignored. In this case, the number of failures (replacements) over time (see **Recurrent Event Data**) is given by a *renewal process* and the mean number of failures over $[0, t)$ is given by the *renewal integral equation*

$$M(t) = F(t) + \int_0^t M(t - t') dF(t') \quad (4)$$

Repairable item. There are different types of repairs (see **Repairable Systems Reliability**). With *minimal repair*, the failure rate after repair is the same as the failure rate of the item immediately before it failed [4]. With *imperfect repair*, the failure rate after repair is less than that just before failure but not as good as that for a new component.

With minimal repair and the repair time negligible in relation to the mean time between failures, failures over time occur according to a *nonhomogeneous Poisson process* [5]. The mean number of failures over $[0, t)$ is given by

$$E[N(t)] = \Lambda(t) = \int_0^t h(x) dx \quad (5)$$

For the case of imperfect repair, the analysis is more complicated. See [6] and references therein for additional details.

Two-Dimensional Failure Modeling

There are two approaches to modeling failures in the 2D case.

Approach 1 (1D Approach). The two-dimensional problem is effectively reduced to a one-dimensional problem by treating usage as a function of age.

First failure. Let $Z(t)$ denote the usage of the item at age t and assume that it is a linear function of t of the form

$$Z(t) = Rt \quad (6)$$

where $R, 0 \leq R < \infty$, represents the usage rate and is a non-negative random variable with a distribution function $G(r)$ and density function $g(r)$.

The hazard function, conditional on $R = r$, is denoted by $h(t|r)$. Various forms of $h(t|r)$ have been proposed, including the linear case given by

$$h(t|r) = \theta_0 + \theta_1 r + \theta_2 t + \theta_3 Z(t) \quad (7)$$

The conditional distribution function of time to first failure is given by

$$F(t|r) = 1 - \exp \left\{ - \int_0^t h(u|r) du \right\} \quad (8)$$

On removing the conditioning, the distribution function for the time to first failure is given by

$$F(t) = \int_0^\infty \left(1 - \exp \left\{ - \int_0^t h(u|r) du \right\} \right) \times g(r) dr \quad (9)$$

Subsequent failures. Under minimal repair, the failures over time occur according to a nonhomogeneous Poisson process [7] with intensity function $\lambda(t|r) = h(t|r)$. Under perfect repair, the failures occur according to the renewal process associated with $F(t|r)$.

The bulk of the literature deals with a linear relationship between usage and age. See, for example [1, 8, 9]. For applications, see [10], which deals with motorcycle failures under warranty, and [8, 11], which deal with automobile warranty data analysis.

Approach 2 (2D Approach).

First failure. Let T and X denote the item age and usage at first failure. Both of these are random variables. T and X are modeled jointly by the bivariate distribution function

$$F(t, x) = P(T \leq t, X \leq x); \quad t \geq 0, x \geq 0 \quad (10)$$

The survivor function is given by

$$\begin{aligned} \bar{F}(t, x) &= \Pr(T > t, X > x) \\ &= \int_t^\infty \int_x^\infty f(u, v) dv du \end{aligned} \quad (11)$$

If $F(t, x)$ is differentiable in both arguments, the bivariate failure density function is given by

$$f(t, x) = \frac{\partial^2 F(t, x)}{\partial t \partial x} \quad (12)$$

Subsequent failures. In the case of nonrepairable items, failed items are replaced by new ones. In this case, failures occur according to a 2D renewal function [4] and the expected number of failures over $[0, t) \times [0, x)$ is given by the solution of the two-dimensional integral equation

$$\begin{aligned} M(t, x) &= F(t, x) + \int_0^t \int_0^x M(t - u, x - v) \\ &\quad \times f(u, v) dv du \end{aligned} \quad (13)$$

Warranty Cost Analysis

In a simple risk analysis, a manufacturer may consider only short- and long-term risks. In warranty analysis, these are represented by (a) expected cost per unit sold and (b) expected cost over the product life cycle (*see Subjective Expected Utility*).

Expected Cost per Unit Sold

Whenever a failed item is returned for rectification action under warranty, the manufacturer incurs various costs – handling, material, labor, facilities, etc. These costs are random variables. The total cost of servicing all warranty claims for an item over the warranty period is the sum of a random number of such individual costs, since the number of claims over the warranty period is also random. The expected warranty service cost per unit is needed in deciding the selling price of the item.

Expected Cost over the Life Cycle of a Product

From a marketing perspective, the product life cycle, L , is the period from the instant a new product is launched to the instant it is withdrawn from the market. Over the product life cycle, product sales (first and repeat purchases) occur over time in a dynamic manner. The manufacturer must service the warranty claims with each such sale. In the case of products sold with one-dimensional nonrenewing warranty, this period is $L + W$, where W is the warranty period.

The expected cost incurred over $[t, t + \delta t)$ depends on the sales over the interval $[t - \psi, t)$, where

$$\psi = \max(0, t - W) \quad (14)$$

Sales over time can be modeled either by a continuous function (appropriate for large volume sales) or a point process (appropriate for small volume sales). Assume that the sales rate is given by $s(t)$, $0 \leq t \leq L$, so that total sales S over the life cycle is

$$S = \int_0^L s(t) dt \quad (15)$$

Assumptions

In developing tractable and reasonable warranty cost models, various assumptions regarding the process are made. These typically include the following:

1. All consumers are alike in their usage. This can be relaxed by dividing consumers into two or more groups of similar usage patterns.
2. All items are statistically similar. This can be relaxed by including two types of items (conforming and nonconforming) to take into account quality variations in manufacturing.
3. Whenever a failure occurs, it results in an immediate claim. Relaxing this assumption involves modeling the delay time between failure and claim.
4. All claims are valid. This can be relaxed by assuming that a fraction of the claims are invalid, either because the item was used in a mode not covered by the warranty or because it was a bogus claim.
5. The time to rectify a failed item (either through repair or replacement) is sufficiently small in relation to the mean time between failures that it can be approximated as being zero.
6. The manufacturer has the logistic support (spares and facilities) needed to carry out rectification actions without delays.
7. The cost of each rectification under warranty (repair or replacement) is modeled by the following cost parameters:
 C_m : cost of replacing a failed unit by a new unit (manufacturing cost per unit)
 C_h : handling cost per claim
 C_r : average cost of each minimal repair.
8. The product life cycle, L , is modeled as a deterministic variable. One can easily relax this assumption and treat it as a random variable with a specified distribution.

9. All model parameters (costs and the various distributions involved) are known.

Modeling Warranty Cost per Unit Sold

In this section and in the following one, the cost analysis for Policies 1–3 is provided. Numerical examples for Policies 1 and 2 are given in the section titled “Examples”. Additional examples for these as well as the analysis and examples for many other warranties may be found in [1, 2, 8–11].

Cost Analysis of Policy 1

Replace by New. Since failures under warranty are rectified instantaneously through replacement by new items, the number of failures over the period $[0, t)$, $N(t)$, is characterized by a renewal process with time between renewals distributed according to $F(t)$. As a result, the cost $\tilde{C}(W)$ to the manufacturer over the warranty period W is a random variable given by

$$\tilde{C}(W) = (C_m + C_h)(N(W)) \quad (16)$$

The expected number of failures over the warranty period is

$$E[N(W)] = M(W) \quad (17)$$

where $M(t)$ is the renewal function given by equation (4). As a result, the expected warranty cost per unit to the manufacturer is

$$C(W) = (C_m + C_h)M(W) \quad (18)$$

Minimal repair. Failures over the warranty period occur according to a nonhomogeneous Poisson process with intensity function equal to the failure rate $r(t)$, and the expected warranty cost to the manufacturer is

$$C(W) = (C_r + C_h) \int_0^W r(x) dx \quad (19)$$

Cost Analysis of Policy 2

In the case of linear rebate function

$$q(x) = \begin{cases} (1 - x/W)P & 0 \leq x < W \\ 0 & \text{otherwise} \end{cases} \quad (20)$$

the warranty cost to the manufacturer is

$$\tilde{C}(W) = C_h + q(T) \quad (21)$$

where T is the lifetime of the item supplied. As a result, the expected cost per unit to the manufacturer is

$$\begin{aligned} C(W) &= E(\tilde{C}(W)) \\ &= C_h F(W) + \int_0^W q(x) f(x) dx \end{aligned} \quad (22)$$

Using equation (20) in equation (22) and carrying out the integration, we have

$$C(W) = C_h F(W) + P \left[F(W) - \frac{\mu_W}{W} \right] \quad (23)$$

where

$$\mu_W = \int_0^W t f(t) dt \quad (24)$$

is the *partial expectation* of T .

Cost Analysis of Policy 3

As mentioned in the section titled “Approach 1 (1D Approach)”, there are two approaches to modeling failures. Approach 1 is more appropriate for the case of repairable products (with minimal repair) and Approach 2 for nonrepairable products.

Approach 1. The product is repairable and the manufacturer rectifies all failures under warranty through minimal repair. In this case, the distribution of failures over the warranty period can be characterized by an intensity function $\lambda(t|r)$. Conditional on $R = r$, we assume a linear intensity function given by equation (7).

Note that conditional on $R = r$, the warranty expires at time W if the usage rate r is less than γ , where

$$\gamma = U/W \quad (25)$$

and at time t_r given by

$$t_r = U/r \quad (26)$$

if the usage rate $r > \gamma$. The expected numbers of failures over the warranty period for these two cases are given by

$$E(N(W, U)|r) = \int_0^W \lambda(t|r) dt \quad (27)$$

and

$$E(N(W, U)|r) = \int_0^{t_r} \lambda(t|r) dt \quad (28)$$

respectively. On removing the conditioning, we have the expected number of failures during warranty and, using this, we find the expected warranty cost to be

$$\begin{aligned} C(W, U) &= [C_r + C_h] \left\{ \int_0^\gamma \left[\int_0^W \lambda(t|r) dt \right] g(r) dr \right. \\ &\quad \left. + \int_\gamma^\infty \left[\int_0^{t_r} \lambda(t|r) dt \right] g(r) dr \right\} \end{aligned} \quad (29)$$

Approach 2. The product is nonrepairable and the manufacturer rectifies all failures under warranty through replacement by new. In this case, the number of failures over the warranty region is given by a 2D renewal process and the expected warranty cost is given by

$$C(W, U) = (C_m + C_h)M(W, U) \quad (30)$$

where $M(W, U)$ is obtained from equation (13).

Examples

The examples that follow illustrate the cost analysis of Policies 1 and 2. In both cases, $F(W)$ is assumed to have a simple form, the exponential distribution, which is appropriate when failures occur at a constant rate. In practice, this is very often not the case, and the Weibull and any of several other alternative distributions are more appropriate [1, 2].

Policy 1. A cell phone is sold with nonrenewing FRW with warranty period W . Failed items are scrapped and replaced by new phones. Suppose that time to failure is exponentially distributed with parameter λ , i.e., $F(t) = 1 - e^{-\lambda t}$ for $t \geq 0$. Then [4] the MTTF is $\mu = 1/\lambda$ and $M(t) = \lambda t$. We further assume that the manufacturer’s total cost of processing a claim is $C_m + C_h = \$37$. From equation (18), the manufacturer’s expected cost of warranty is

$\$37\lambda W$. Suppose the *MTTF* of the phone is 4 years (so $\lambda = 0.25$). If a 90-day warranty ($W = 0.25$ years) is offered, then the expected warranty cost is \$2.31 per unit sold. For a 6-month warranty, this cost would be \$4.63. If the phone is priced at \$100, these would usually be considered reasonable warranty costs.

Policy 2. An automobile battery is sold with a pro rata warranty. For purposes of illustration, we assume that it is a rebate warranty (Policy 2) with linear rebate function and that the time to failure of the battery is exponentially distributed. The model for manufacturer's cost of warranty is given in equation (23). For the exponential distribution [1, p. 174], $\mu_W = \lambda^{-1}(1 - (1 + \lambda W)e^{-\lambda W})$. Suppose that the *MTTF* of the battery is 5.77 years (which corresponds to a median lifetime of 4 years) and that $W = 2$. Then $F(2) = 0.293$ and $\mu_W = 0.275$.

If $C_h = \$10$ and the selling price is $P = \$100$, the cost of warranty is $\$10(0.293) + 100(0.155) = \18.43 . The corresponding cost if $W = 1$ is \$9.77. Both of these costs are very substantial. The cost can be reduced in a number of ways – increasing reliability, increasing the *MTTF*, decreasing the warranty period, selecting a different warranty policy, and so forth.

Warranty Cost over Life Cycle

Consider the case in which the product is non-repairable and the life cycle L exceeds the warranty period W . Since the manufacturer must provide a refund or replacements for items that fail before reaching age W , and since the last sale occurs at or before time L , the manufacturer has an obligation to service warranty claims over the interval $[0, L + W]$. Life cycle costs for Policies 1 and 2 will be considered. Some results for Policy 3 can be found in Blischke and Murthy [1, Sections 8.3.1 and 8.4.1].

Cost Analysis for Policy 1

Since failed items are replaced by new ones over the warranty period, the demand for spares in the interval $[t, t + \delta t)$ is due to failure of items sold in the period $[\psi, t)$, where ψ is given by equation (14). It can be shown (details of the derivation can be found

in Chapter 9 of [1]) that the expected demand rate for spares at time t , $\rho(t)$, is given by

$$\rho(t) = \int_{\psi}^t s(x)m(t-x) dx \quad (31)$$

where $m(t)$ is the renewal density function given by

$$m(t) = \frac{dM(t)}{dt} = f(t) + \int_0^t m(t-t')f(t') dt' \quad (32)$$

The expected total number of spares required to service the warranty over the product life cycle, *ETNS*, is given by

$$ETNS = \int_0^{L+W} \rho(t) dt \quad (33)$$

and the total expected warranty cost over the product life cycle is given by

$$LC(W, L) = (C_m + C_h) \int_0^{W+L} \rho(t) dt \quad (34)$$

Cost Analysis for Policy 2

Under Policy 2 the manufacturer refunds a fraction of the sale price upon failure of an item within the warranty period. In order to carry this out, the manufacturer must set aside a fraction of the sale price. This is called *warranty reserving*. We assume a linear rebate function. The rebate over the interval $[t, t + \delta t)$ is due to failure of items that are sold in the interval $[t - \psi, t)$, where ψ is given by equation (14). Let $v(t)$ denote the expected refund rate (i.e., the amount refunded per unit time) at time t . Then it is easily shown that

$$v(t) = P \int_{\psi}^t s(x) \left(\frac{t-t'}{W} \right) f(t-t') dt' \quad (35)$$

for $0 \leq t \leq (W + L)$. (For details, see Chapter 9 of [1].) The expected total reserve needed to service the warranty over the product life cycle is given by

$$LC(W, L) = \int_0^{W+L} v(t) dt \quad (36)$$

Concluding Remarks

The cost analysis of many other types of warranty policies can be found in [1] and in more recent

papers; references to some of these can be found in [12]. This type of analysis is carried out during the front-end (feasibility) stage of the new product development process. Model selection and parameter values are based on similar products, expert judgment, etc. For more on this, see [13], which looks at warranty management from a product life cycle perspective. Once the product is launched, warranty claims provide data for assessing the models and updating the warranty cost estimates. For more on this, relevant references can be found in [12, 13].

End Notes

Water Pollution Risk

Water is a necessity for all forms of life. Water is used by plants and animals to sustain their lives. In addition, man needs water for domestic purposes (food, cooking, drinking, cleaning, etc.) and for his industrial and agricultural activities. Vegetation not only uses water to carry food materials but uses it as a nutrient for its growth. Water acts also as an environment in which aquatic plants and animals live, and it is the bearer of nutrients that produce organic materials from inorganic materials through primary production that forms the base of the food chain. To a large extent, water pollution is mainly the consequence of this diverse use because water becomes the recipient of human and animal waste. For example, it has been estimated by Gray [1] that approximately 1 million cubic meter of domestic and 7 million cubic meter of industrial wastewater is produced daily in the United Kingdom. In addition to this volume, runoff from paved areas and roads and infiltration water produce over 20 million cubic meter of wastewater requiring treatment each day. To cope with this immense volume, the commitment of substantial technical and financial resources to construct and operate large number of sewage and wastewater treatment plants is required. The list of threats to water quality related to human and ecosystem health is immense. Among the chief threats it is possible to identify the following: pathogens, biological toxins, chemical toxics, nutrients, acidification, endocrine disrupting substances, municipal and industrial waste, and water quantity changes affecting water quality due to climate change, diversions, and extreme events.

It is likely that humans have always been concerned about the quality of the water they use to meet their domestic needs. However, water contamination and water protection have become a major concern since John Snow's [2] famous conclusion that water from a public pump was the cause of the cholera epidemic in London in 1854. This was reported almost 30 years prior to the discovery of cholera's causative agent by Robert Koch in Egypt in 1883. The important aspect of John Snow's discovery is that a substance does not need to be necessarily visible or without discernible taste or odor to be identified as harmful. Indeed, the most serious contaminants (viruses and toxic substances) are those that are not

directly detectable by human senses. Technological advances in measurements have been responsible for discovering the presence of many unknown hazards and quantifying their levels in various environmental media (air, water, and soil). Examples include pathogenic bacteria, viruses, and trace toxic contaminants. With the awareness of these pollutants entering water systems, risk analysis has become an essential tool to detect, identify, quantify, and manage their existing and potential threats. As a result there is mounting evidence that exposure to higher levels of water pollution is associated with adverse effects on the health of human and all forms of aquatic life.

This article is not intended to discuss the risks from all water pollution sources; it is restricted to the risks posed particularly to human health. For this purpose, a pollutant is defined as any substance or agent when introduced to a water system at a level that causes or expected to cause adverse consequences to any of the water's beneficial functions. The goals of water pollution risk analysis are to assess, predict, and control existing and potential adverse impact of water contamination. The emphases here are on the quantitative statistical aspects. Specifically, the discussion centers on two classes of pollution types: persistent toxic substances and microbiological contamination (MC).

Persistent Toxic Substances (PTS)

Persistent toxic substances (PTS) are chemical agents that are able to retain their molecular integrity and hence their physical, chemical, and functional characteristics in the aquatic environment. Once a PTS chemical enters an environment, it will be transported and distributed within that environment for a long period of time. The Great Lakes Water has been found to contain thousands of PTS, including polychlorinated biphenyls (PCBs), (*see* **Polychlorinated Biphenyls**) dichloro-diphenyl-trichloroethane (DDT), mirex and mercury [3]. The health of millions of Canadian and United States citizens is at risk because they depend on the Lakes as a source for drinking water and for their recreational activities. Furthermore, these substances tend to bioaccumulate through the food chain and become a serious threat to those who diet on fish caught from the Lakes' contaminated water. Some PTS agents such as mercury, lead, and cadmium (*see* **Lead**; **Methylmercury**) occur naturally in the environment, while others are the product

of anthropogenic activities. Canada and United States have the goal of zero discharge of PTS in the Great Lakes but this will not eliminate the chemicals from the water: the historic burden of these substances in the Lakes' contaminated sediment and the long-range airborne transport of these chemicals helps motivate their primary moniker, "persistent". The approach used by Canada to control the impacts of PTS is the issuance of fish consumption advisories [1] that take into account the variations in the concentrations of the contaminants in different-sized fish of various species.

Figure 1 shows the empirical cumulative distribution function (EDF) of the concentration of total PCBs in the tissues of samples of trout caught from Lake Ontario and Superior in the summer of 2001 along with the Ontario government's [4] critical level advisory for PCBs consumption. This figure illustrates two points:

Figure 1 The EDF of PCBs concentration in fish tissue from Lakes Ontario and Superior

1. The concentration level is higher in Lake Ontario than that found in fish from Lake Superior, highlighting the persistence nature of PCBs and their accumulation from all upstream sources before reaching Lake Ontario.
2. There is a greater risk associated with consuming fish from Lake Ontario than that associated with consuming fish at the same age caught in Lake Superior.

Since it is impossible for individuals to measure levels of contaminants in the fish available for consumption, it is therefore necessary to relate the level of contamination to easily and inexpensive measurable fish characteristics. There are three possible surrogate characteristics that meet these requirements: age, weight, and length. These are positively correlated with the level of the bioaccumulation of contaminants. Usually, the advisory critical level is stated in terms of weight and/or length because the latter are easy to measure. Figure 2 shows the association between age and PCBs level in Lake Ontario. The advisory usually includes the specification of the maximum number of meals allowed during a standard time period and size of portion to be consumed during a meal. In addition, the advisory frequently states different restriction limits for different population group: for example, lower limits may be stated for children and pregnant women.

To describe a model for representing the dependence of PCBs concentration on age for Lake Ontario, let x_t be the observed concentration of PCBs in a fish at age t and let X_t be its corresponding random variable, then a possible model for X_t is

$$X_t = b(1 - \exp(-\lambda t^m)) + \varepsilon_t \quad (1)$$

Figure 2 Measured and modeled PCBs concentration in fish from Lake Ontario

where b , λ , and m are unknown parameters and ε_t is a zero-mean random variable with constant variance. Note that b represents the maximum PCBs accumulation and λ represents the rate of accumulation. It should be noted that at $t = 0$, X_t will have mean zero, while when $m = 0$, the mean is a constant, independent of age. Figure 2 shows the fitted model when $m = 1$ (dotted curve) and when m is estimated along with the other two parameters (solid curve). The results indicate that m is significantly different from 1. The model could also be used to generate the PCBs distribution for a specified age. Figure 3 shows the model-based simulation of this distribution for ages 3, 7, and 14 years. The figure can be used to determine the degree of risk associated with each age and is thus useful for setting an appropriate advisory consumption level.

Microbiological Contaminants (MC)

The other example we consider is related to the risk associated with drinking and recreational use when the water source is contaminated by pathogenic organisms that cause illness and sometimes death in the exposed population. Examples of potentially lethal diseases caused by contaminated water include typhoid fever, typhus, cholera, and dysentery. Waterborne pathogens can pose threats to drinking water supplies, recreational waters, source waters for agriculture, and aquaculture, as well as to aquatic

ecosystems and biodiversity. Disease outbreaks are widespread in underdeveloped countries but also still occur in developed countries [5] despite the great efforts and resources taken to prevent microbial pollution and safeguard water supplies. Examples of outbreaks in developed countries are as follows:

1. The recent and fatal epidemic that occurred in Walkerton, Ontario, Canada, in May 2000 where, in that small town of 4800 residents, 2200 residents became seriously ill and 7 died. As a result a public inquiry was established by the Government of Ontario to address the causes of the outbreak. Mr. Justice Dennis O'Connor [6] headed the inquiry and his report summarizes the deficiencies involved from protecting water sources to the delivery of safe drinking water to the residents (O'Connor [6]). Hrudey *et al.* [5] compare the Walkerton epidemic to other outbreaks in the developed countries.
2. The Milwaukee outbreak that resulted in 54 deaths and over 400 000 cases of illness (Hoxie *et al.* [7]).
3. The spread of cholera across Iraq after it was detected earlier in the north of the country as reported in September 21, 2007 by *The New York Times*.

The catalog of waterborne pathogens is long, and it includes many well-known organisms as well as far larger numbers of more obscure organisms.

Figure 3 Simulated PCBs distribution in the trout tissue from Lake Ontario

Table 1 The 1986 EPA criteria for recreational waters

Water type	Indicator	Geometric mean	Single sample maximum
Marine	<i>Enterococci</i>	35	104
Fresh	<i>Enterococci</i>	33	61
	<i>E. coli</i>	126	235

Waterborne pathogens include viruses (e.g., hepatitis A, poliomyelitis); bacteria (e.g., cholera, typhoid, coliform organisms); protozoa (e.g., *cryptosporidium*, *amebae*, *giardia*); worms (e.g., *schistosomia*, guinea worm); etc. To enumerate all waterborne harmful organisms would require complex, time-consuming, and expensive procedures to be performed on each water sample analyzed. These difficulties led to the development of microbiological fecal pollution indicators. Coliform bacteria group was adopted as indicator in 1914 (Pipes *et al.* [8] and Olivieri *et al.* [9]) by the United States for monitoring drinking water. The use of coliforms as an index of water quality has been criticized, and currently researchers in Canada and United States are investigating the potential use of more appropriate indicators. The maximum microbiological contaminant levels (MCLs) approach was adopted by the United States Environmental Protection Agency (US EPA) as a legal requirement [6]. The MCLs state (Pipes [10]) that if a membrane filters method is used,

1. the arithmetic mean coliform count of all standard samples examined per month shall not exceed 1/100 ml and
2. the number of coliform bacteria shall not exceed 4/100 ml in
 - (a) more than one sample when less than 20 samples are examined or
 - (b) more than 5% of the samples if at least 20 samples are examined.

When the coliform count in a single sample exceeds 4/100 ml, at least two consecutive daily check samples shall be collected and examined until the results from two consecutive samples show less than one coliform bacterium per 100 ml.

El-Shaarawi and Marsalek [11] discussed various sources of uncertainties associated with the application of guidelines and criteria in water quality monitoring. Carbonez *et al.* [12] assessed the performance of the two rules of MCLs stated above and

concluded that it is sufficient to use only the first rule that requires the placing of an upper limit on the mean coliform count.

The 1986 EPA for primary contact recreational use criteria are listed in Table 1. It should be noted that the two rules are also involved here: the geometric mean rule and a single sample rule. Also there are two indicator organisms (*enterococci* and *Escherichia coli*) in the case of freshwater but for marine waters only *enterococci* is used. These limits were derived based on the epidemiological studies reported by Cabelli [13]. Another difference between the MCLs, which is designed for drinking water and for recreational water, is the placement of an upper limit on the geometric mean instead of setting the limit on the arithmetic mean.

A simple way to evaluate the need for the two rules is to assume that the lognormal distribution can be used as a model for the density of the indicator organism in water samples (El-Shaarawi [14]). It should be mentioned that the negative binomial distribution is also frequently used as a model for bacterial counts (El-Shaarawi [15] and El-Shaarawi *et al.* [16]). Let X_i be the random variable representing the log density, which is assumed to have a normal distribution with mean μ and standard deviation σ . The two rules require that when n observations are available their mean $\bar{X}$ should be smaller than the threshold b and the largest observation $X_{(n)}$ should be smaller than a .

Let $\xi = \frac{b-\mu}{\sigma}$, $\eta = \frac{a-\mu}{\sigma}$, and $g = \frac{\varphi(\xi)}{\Phi(\xi)}$, where $\varphi(\xi)$ and $\Phi(\xi)$ are the density and distribution functions of the standard normal. Then, as a criterion for comparing the two rules we use the log ratio of the probabilities of declaring that the water source is unfit for recreational activities, i.e.,

$$\rho = \log \frac{1 - \text{prob}(X_{(n)} < b)}{1 - \text{prob}(\bar{X} < a)} = \log \frac{1 - \{\Phi(\xi)\}^n}{1 - \Phi(\sqrt{n}\eta)} \quad (2)$$

The above criteria could be used to estimate the expected level of the indicator organism when the two

Table 2 Expected values of the density of indicator organism as a function of sample size

<i>N</i>	5	10	15	20	25	30	35	40	45	50
Mean	43.67	39.29	37.72	36.87	36.33	35.95	35.66	35.44	35.26	35.11

rules are equally effective in detecting the existence of water quality problems at a specified level. For example, if it is desirable to estimate the expected value that corresponds to a 0.95 level for various sample sizes, then we need to compute μ from the following expression

$$\lambda = \frac{\xi}{\eta} = \frac{\log(b) - \mu}{\log(a) - \mu} = \frac{\Phi^{-1}(0.95^{1/n})\sqrt{n}}{\Phi^{-1}(0.95)} \quad (3)$$

for various values of n . Then, the corresponding indicator level is $\exp(\mu)$. Table 2 gives these values for several sample sizes.

Wear

In material sciences, wear is defined as a dimensional loss of a solid resulting from its interaction with its environment. Wear processes include several different physical phenomena, e.g., erosion, corrosion, fatigue, adhesive wear, and abrasive wear. In risk and reliability engineering, the term *wear* (see **Imprecise Reliability; Reliability Data; Bayesian Statistics in Quantitative Risk Assessment**) is used in a broader sense and often refers to the deterioration of an item or equipment with usage and age, see, e.g. [1–3]. In this broader framework, wear represents a larger array of physical phenomena due to, e.g., mechanical and/or chemical actions such as fatigue, fatigue crack growth [4, 5], fracture, creep, erosion, corrosion, alteration of material properties with time, temperature, and light. Cutting tools [6], hydraulic and concrete structures [7, 8], brake linings, airplane engine compressor blades [9], corroding pipelines [10], and rotating equipments are examples of items that suffer increasing wear with usage and age.

For a given item, wear accumulates over time, contributes to the aging process and can be seen as the failure-generating mechanism: the original properties of the item change, which may lead to failure (when the wear level exceeds a given limit) if proper maintenance action is not carried out, to higher operating costs, and to a more intensive maintenance activity. To assess the reliability of a wearing system, to evaluate its life-cycle cost, or to optimize its design and maintenance, it is of primary interest to be able to predict its wear behavior, and we need models for this purpose. However, since the physical phenomena involved are very complex, it is almost impossible to derive a complete wear model on the basis of well-known physical laws, except for very local phenomena and it is thus necessary to use phenomenological models (see **Experience Feedback**). Since the wear model should also take into account the uncertainty, the variations around a mean behavior between items, and, if possible, the temporal variability of the deterioration, we have to use probabilistic phenomenological models [1, 11, 12]. Such models can then be used to estimate the time at which a given wear level is reached or to characterize the residual life of the wearing item. We can distinguish two approaches in probabilistic wear modeling: the lifetime modeling approach and

models based on time-dependent stochastic processes. The sections titled “Wear Modeling Using Lifetime Distributions” and “Wear Modeling by Stochastic Processes” propose synthetic, critical descriptions of these two wear-modeling options. The section titled “Application in Reliability and Maintenance” gives some examples of application of wear models in reliability and maintenance.

Wear Modeling Using Lifetime Distributions

In reliability theory [13, 14], we use a lifetime distribution (see **Risk Classification/Life; Mathematics of Risk and Reliability: A Select History**) to represent the random behavior of the time to failure T of an item. If $f(t)$ denotes the probability density function of the time to failure, and $F(t) = \mathbb{P}(T \leq t)$ the probability distribution function, the failure-rate function $\lambda(t)$ of the item is given by

$$\lambda(t) = \frac{f(t)}{1 - F(t)} = \frac{f(t)}{\bar{F}(t)} \quad (1)$$

The survival (or reliability) function of the item is directly obtained from equation (1) by integration and exponentiation, and we have

$$\bar{F}(t) = \exp \left\{ - \int_0^t \lambda(s) \, ds \right\} \quad (2)$$

The quantity $\lambda(t) \, dt$ can be interpreted as the conditional probability that an item that has survived until time t will fail in the next time interval $[t, t + dt]$. Following this interpretation, it is natural that for wearing items, the failure rate is increasing. The classical “bathtub” curve (see **Accelerated Life Testing**) sketches the typical evolution of an item as a function of time that can be divided into three periods: the burn-in period, the useful life, and the wear-out period during which the failure rate increases under the effect of cumulative wear (see Figure 1). At this stage, assumptions on the wear behavior of the item are used to choose the general form of its failure-rate function. Lifetime distributions with an increasing failure rate (IFR) (see **Systems Reliability; Repair, Inspection, and Replacement Models**), known as *IFR lifetime distributions* [13, 14], are adapted to model the reliability behavior of wearing items. The Weibull

Figure 1 The bathtub curve

distribution (for $\alpha > 1$) and the gamma distribution (for $\alpha > 1$) both belong to the IFR distribution family.

Weibull Distribution

The Weibull distribution is one of the most widely used lifetime distributions because of its flexibility: an appropriate choice of parameters permits one to model different types of failure-rate behaviors. The failure-rate function given by

$$\lambda(t) = \alpha\beta^\alpha t^{\alpha-1} \quad (3)$$

is increasing for a shape parameter $\alpha > 1$; hence, the Weibull distribution with $\alpha > 1$ is often chosen to model the failure behavior of a wearing item.

Gamma Distribution

The probability density function for a gamma distribution is given by

$$f(t) = \frac{1}{\Gamma(\alpha)} \beta^\alpha t^{\alpha-1} e^{-\beta t} \quad (4)$$

It can be shown that the gamma distribution is IFR for a shape parameter $\alpha > 1$. The gamma distribution is also particularly adapted to the failure modeling of an item subject to wear because, for an integer value of α , it corresponds to an item whose wear level increases under the effect of a series of shocks occurring according to a homogeneous Poisson process with rate β , leading to a failure after shock α .

This modeling procedure has the main drawback of relying on a static binary “black box” approach.

The considered item is assumed to be either in the running state or in the failed state, regardless of its intermediate wear level and the dynamic failure-generating mechanism resulting from accumulated wear is not explicit in the model. A more dynamic and flexible approach to reliability modeling of wearing items is thus needed to take into account the temporal variability of deterioration and to elaborate wear-dependent reliability models: wear models based on stochastic processes offer such an alternative.

Wear Modeling by Stochastic Processes

For a number of applications, data are available from sensors or monitoring devices. This allows one to obtain measures describing the changes in the state of an item over time or with usage. From a modeling point of view, the engineering approach tries to describe by theory and testing, the physics of the dynamics to failure of the system. Such a methodology requires exact description of behavior and has already proved its worth in many cases, but makes it difficult to capture fluctuating operating environment. Two items of the same type with the same load can still show different deterioration rates. The engineering approach might work for tests in controlled laboratory environments. The results, *in situ*, will have a certain scatter and noise. At that instant, a stochastic approach that is presumed to describe the failure-generating mechanism under study might provide interesting results. Stochastic processes are particularly relevant to such a description, especially for items operating under a dynamic environment. They jointly incorporate the evolution of degradation with the temporal uncertainty and have proved to be better wear models than a random variable model

when the variability in degradation, thus in lifetime, is high [15].

Assuming the degradation of the system is measured on an increasing scale, let X_t denote the state of an item at time t . The internal wear of the item over the time interval $[s, t]$ is defined as an increment $X_t - X_s$ describing the degradation caused by continuous use over $[s, t]$. In most applications (e.g., erosion, corrosion), the wear of a nonmaintained system is a nondecreasing phenomenon. However, there are many situations in which the wear need not be increasing (e.g., because of possible healing of fatigue cracks). Various models that have been considered are based on the concept of accumulated damage, viewing the degradation and resulting failure of the item as the result of accumulation of wear over the lifetime. Shocks may occur to the system, and each shock may cause a random amount of wear, which accumulates additively. Most of the stochastic processes used for wear modeling proceed from the class of Lévy processes (see **Lévy Processes in Asset Pricing**), which contains tractable continuous-time processes with independent and stationary increments [16]. Using the class of Lévy processes retains the Markov property. Three Lévy processes can be considered as the main basic elements for stochastic wear modeling, each of them having explicit descriptions and possible extensions: the compound Poisson process (jump process [17, 18]), the gamma process (jump process [11, 19, 20]) and the Wiener process (with continuous sample paths [21–23]). A short description is given below.

Compound Poisson Process

The compound Poisson process (see **Ruin Probabilities: Computational Aspects; Volatility Smile**) can be used to model wear that accumulates in discrete amounts at isolated points in time, due to shocks. The deterioration $(X_t)_{t \geq 0}$ is described as a sum of wear increments W_i occurring at discrete times t_i :

$$X_t = \sum_{i=1}^{N_t} W_i \quad (5)$$

where $(N_t)_{t \geq 0}$ is a Poisson process and $(W_i)_{i=1,2,\dots}$ is a family of independent and identically distributed random variables, independent of the Poisson process. One of the first attempts to model wear as a stochastic process may have been with compound

Poisson Process [17]. Further studies can be found in [24] with extensions to continuous-wear processes.

Gamma Process

The gamma process (see **Large Insurance Losses Distributions; Repairable Systems Reliability**) is appropriate to model a nondecreasing deterioration. It is a stochastic continuous-time process with independent nonnegative increments having a gamma distribution [19]. The amount of wear $X_t - X_s = W_{t-s}$ over the time interval $[s, t]$ follows a gamma distribution $\text{Ga}(\alpha(t-s); \beta)$ with a shape parameter depending on $t-s$. The mean and variance are respectively

$$\mu_w = \frac{\alpha(t-s)}{\beta} \text{ and } \sigma_w^2 = \frac{\alpha(t-s)}{\beta^2} \quad (6)$$

As a limiting case of the compound Poisson process, the gamma process implies a wear increasing with frequent occurrences of very small increments, leading to practical uses in modeling erosion or corrosion, for example.

Wiener Process

The Wiener process (see **Lifetime Models and Risk Assessment**) (Brownian motion with drift) is a nonmonotonic process with continuous sample paths. The degradation at time t is described by a Wiener process with drift μ and variance σ if

$$X_t = \sigma B_t + \mu t \quad (7)$$

where B_t is the standard Brownian motion. A large drift and small variance parameters are often used to approximate monotonicity. One of the main advantages of the Wiener process for wear modeling is that it has been extensively studied in the mathematical literature. For example, the first passage time distribution is known to be the generalized inverse Gaussian distribution [25].

Covariates

Multiple sources of information can be used to characterize the wear of an item in time. Additional environmental and explanatory factors such as temperature, pressure, light, etc. may influence the degradation and lead to substantial heterogeneity

between the degradation paths. Describing failure-generating mechanisms by stochastic processes with covariates is particularly relevant to items operating under dynamic environment when the stresses are partly induced by environmental factors (or covariates) varying over time [2]. Wear stochastic processes with covariates can be used for internal stresses that change the rates and the modes by which the item degrades to failure. In these models, the degradation is described by the process $(X_{t,\theta})_{t \geq 0}$, where t is the time and θ is some possibly multidimensional random variable.

A lot of wear stochastic processes with covariates are extensions of the gamma process or of the Wiener process with linear drift. The consequences of such extensions are mainly an increasing number of parameters and possible related estimation troubles. In a gamma process, the covariates are mostly incorporated through the shape parameter α [11]. In [26], an accelerated life model is used, replacing αt by $\alpha(t \exp(\theta^T x))$, whereas in [20], the scale parameter is considered as a function of covariates $\beta(\theta)$ and can be replaced by $z\beta(\theta)$ where z is a random effect.

Multivariate stochastic processes like the Markov additive processes (MAP) [18] provide an extended framework for modeling degradation of items, given the stochastic behavior of covariates. Covariate processes that drive the wear are referred to in the engineering literature as “excitation processes”. MAP can be considered as extensions of compound Poisson processes [27].

Application in Reliability and Maintenance

Application in Reliability

One of the advantages of using a stochastic wear process is to develop a degradation-based reliability model instead of a failure-based reliability model [2, 28–30]. If one considers that the item fails as soon as the wear level X_t exceeds a given threshold L , the lifetime of the system is described by the random variable

$$\sigma_L(x) = \inf\{t : X_t > L\} \quad (8)$$

i.e., the first hitting time of the level L for the wear process X_t . The main difficulty with this approach is, then, to derive the lifetime distribution for $\sigma_L(x)$,

i.e., to establish an expression for the item reliability at time t :

$$\bar{F}^x(t) = \mathbb{P}(\sigma_L(x) > t | X_0 = x_0) \quad (9)$$

The evaluation of equation (9) requires calculation of the distribution of the first passage time of the process $(X_t)_{t \geq 0}$ above the level L , which is, in general, difficult for arbitrary stochastic processes. Closed form solutions or explicit results for the properties of the lifetime distribution in equation (9) can be obtained under simplifying assumptions [16, 19, 24, 31–33], but in the general case, for the estimation and characterization of the lifetime in equation (9) we have to resort to simulation-based techniques. As an example, considering the gamma process and given $X_0 = 0$, the usual distributions are given as follows:

- Density function of the wear level at time t :

$$f_w(u) = f_{\alpha t, \beta}(u) = \frac{\beta^{\alpha t} u^{\alpha t - 1}}{\Gamma(\alpha t)} \exp(-\beta u) \mathbb{I}_{u > 0} \quad (10)$$

- Cumulative lifetime distribution at time t :

$$F_\sigma(t) = \mathbb{P}(X_t \geq L) = 1 - F_{\alpha t, \beta}(L) \quad (11)$$

- Density function of the lifetime:

$$\begin{aligned} f_\sigma(t) &= - \frac{dF_T(t)}{dt} \\ &= \int_0^L \alpha f_{\alpha t, \beta}(s) \left(\frac{\Gamma'(\alpha t)}{\Gamma(\alpha t)} - \log(\beta s) \right) ds \end{aligned} \quad (12)$$

where $F_{\alpha t, \beta}$ is the distribution function of the gamma density probability function $f_{\alpha t, \beta}$ and $\Gamma(u)$ is the gamma function. The probability density function of the hitting time σ_L , given by equation (12), has no closed form expression and has to be computed numerically when required.

Traumatic events causing the failure of the item occurring, for example, as a Poisson process with a “killing” rate k depending on the item’s level of wear can be considered to make these models even more general [2]. Finally, this stochastic process-based approach, even if mathematically more demanding, leads to reliability models with a greater flexibility to fit failure data and to include environmental explicative variables as covariates. These models

thus offer the possibility to integrate the available information on dynamic environment and changing operating conditions of the considered item. They extend the range of possible applications of reliability models; for example, they can be used for a prognostic purpose, i.e., to predict the future wear behavior and to estimate the reliability and residual life of an item from wear measurements [28, 34]. Moreover, these wear-based reliability models include the classical failure-based lifetime models (such as Weibull or gamma distributions) as particular cases [2, 3]. To illustrate this last point, consider the “limit case” example given in [2] of an item subject to a wear, modeled by a deterministic diffusion process $X(t)$ satisfying the integral equation

$$X(t) = \int_0^t \mu(X(s)) ds + x_0 \quad (13)$$

The item reliability is then obtained as

$$\bar{F}^x(t) = \exp \left\{ - \int_0^t k(X(s)) ds \right\} \mathbb{I}_{\sigma_L(x) > t} \quad (14)$$

which shows that for a deterministic diffusion wear, the failure rate of the item at time t equals the wear-dependent killing rate at this time.

Application in Maintenance

On a wearing item, maintenance is necessary to control the wear level and to restore the item to a state in which it can perform correctly its required function. For classical time-based and age-based maintenance policies, the times between maintenance

actions (inspections, repairs, replacements, and so on) are determined using a prior knowledge given by the lifetime distribution of the maintained item. However, for a wearing item, when the wear level can be directly or indirectly monitored, it is preferable to choose a condition-based maintenance strategy and to base the maintenance decision on the observed wear level. The decision problem to solve is to determine sequentially the optimal inspection schedule and the optimal maintenance action to be carried out on the item at a given time. Here, a wear model is necessary to correctly interpret the raw wear measurements, to forecast the future behavior of the wearing system after a maintenance action, to assess the effects of a maintenance decision, and to optimize the condition-based maintenance policy parameters. Among the main advantages of a condition-based maintenance approach based on wear modeling, we mention the following:

- it has the capacity to adapt to the temporal variability of the wear evolution, e.g., an aperiodic inspection schedule (a more deteriorated system is inspected more frequently) or a proportioned wear level reducing maintenance operation;
- it has the ability to represent general maintenance actions (whose effect is between as-good-as-new replacements and as-bad-as-old minimal repairs) to control the wear of the item around a level where both preventive and corrective maintenance costs and operating costs reach an optimal balance.

As an example of such a condition-based maintenance policies, Figures 2 and 3 show the stochastic

Figure 2 Wear model and condition-based maintenance policy

Figure 3 Structure of the condition-based maintenance policy

wear model and the maintenance policy structure used to schedule inspections, partial preventive repairs, and as-good-as-new preventive replacements in the condition-based maintenance model presented in [35]. The developed maintenance cost model allows the optimal tuning of the wear thresholds of the policy structure (multilevel control limit rule). See [36–42] for other examples and [11] for a complete review of the use of gamma wear processes in condition-based maintenance models.

Weather Derivatives

Historical Perspective

Weather risks are unpredictable fluctuations in cash flows caused by noncatastrophic weather events such as temperature, rainfall, snowfall, and humidity. Weather risks are in general low loss but high occurrence events and are covered by weather derivatives. In contrast, catastrophic (CAT) risks such as tornadoes, wind storms, and tsunamis are usually covered by weather insurance (*see Nonlife Insurance Markets; Large Insurance Losses Distributions; Risk Classification/Life; Ruin Probabilities: Computational Aspects*).

Weather risks can have large impacts on business activities. It is estimated that about 30% of the US economy faces the challenge of weather risks. For example, agricultural outputs and earnings of energy industries are affected by weather conditions. If a summer month is unusually cool, then profits of energy companies are adversely affected owing to the decreased demand of air conditioning. It is therefore necessary to hedge weather risks due to unexpected weather conditions (*see Statistical Arbitrage*). In July 1996, the first weather derivative product was introduced when Aquila Energy structured a dual-commodity hedge for Consolidated Edison (ConEd) Company. The transaction involved ConEd's purchase of electric power from Aquila for the month of August in 1996. A weather clause was embedded into the contract. Aquila would offer a discount to ConEd if August turned out to be cooler than expected. Subsequently, weather derivatives slowly began trading over the counter in 1997. The Weather Risk Management Association (WRMA) was found in 1999. It plays an important role in developing the weather market. WRMA coordinates with the National Oceanic and Atmospheric Administration (NOAA) and the National Weather Service (NWS) to improve weather reporting and data collection (*see Natural Resource Management*). It extends the market to different commercial areas, such as banking, agriculture, energy and trading, and organizes regular meetings and conferences in Europe, Asia, and North America (*see WRMA homepage: <http://www.wrma.org>*).

As the market for weather-related products expanded, Chicago Mercantile Exchange (CME) introduced the first exchange-traded weather futures contracts (and corresponding options) in 1999 and launched weather contracts in October 2003. CME now launches weather contracts in more than a dozen United States cities and in several European and Japanese cities.

The weather market in 1998 was estimated at US \$500 million and it has grown to about US \$5 billion today. The weather derivatives market has become the fastest growing derivatives market (*see CME homepage: <http://www.cme.com/>*).

Weather Derivatives

Definition of Weather Derivatives

Weather derivatives are contingent securities that offer prespecified payments based on how an underlying weather index differs from a prespecified strike value. A typical weather derivative consists of several components as follows:

- *Weather station*
All weather contracts are based on the observations of one or more specific weather stations.
- *Period*
It includes specific start and end date of contract. The length is usually either a month or a season.
- *Underlying index*
It is used to define the payoff of a weather contract. Popular indexes include heating degree days (HDD), cooling degree days (CDD), average temperature, rainfall, snowfall, and humidity. Among them, most trading index is temperature-related derivatives and most contracts are written on either HDD or CDD. Specifically, the HDD index is defined as the sum of the extent to which daily degree average temperatures below the 65°F benchmark while CDD index is the sum of the extent to which degree daily average temperatures above the 65°F benchmark. They are defined as follows:

$$\text{HDD} = \sum \max\{65 - T_i, 0\}, \quad i \in \text{prespecified period}$$

$$\text{CDD} = \sum \max\{T_i - 65, 0\}, \quad i \in \text{prespecified period}$$

where T_i is the average temperature of the i th day.

Table 1 Atlanta February HDD swap

Reference weather station	Atlanta Peachtree Airport (WBAN: 53863)
Period	February 1–28, 2006
Tick size	\$500 per HDD
Fixed rate	1000
Actual accumulated HDD	1300
Payoff at maturity for buyer	$(1300 - 1000) \times 500 = \$150\,000$

- *Tick size*

Prespecified amount attached to each unit of index value.

As an example, consider the contract listed in Table 1.

Weather Derivatives versus Traditional Derivatives

Weather derivatives differ from traditional derivatives for several reasons. While traditional derivatives can be priced using Black–Scholes model, pricing of weather derivatives is more trickier.

First of all, underlying assets such as stocks or currencies are easily available in the spot market for traditional derivatives. In contrast, temperature, rainfall, and snowfall are all nontradable assets. Second, although the weather derivative market has been growing gradually, it is unlikely that it will be as liquid as traditional markets due to its location-specific nature. According to US-based Futures Industry Association (FIA), over 90% of global derivatives trading is in financial derivatives while less than 0.02% is in weather derivatives.

Valuation of Weather Derivatives

People are interested in valuation of weather derivative contracts for three main reasons. The first one is to determine an appropriate strike or an appropriate option premium. The second one is that once a contract has been traded, it is important to know the current value of holdings based on the latest weather conditions. The third one is that external regulators often need to monitor the risk a weather trading organization faced due to the traded contracts. To value weather contracts, there are several possibilities.

Actuarial Pricing

Weather contracts can be valued on the basis of the probabilities of all possible outcomes. This is usually the starting point of all weather option valuation and is commonly known as *actuarial pricing* (see **Insurance Pricing/Nonlife**). Actuarial pricing is performed by using historical meteorological data and meteorological forecasts to predict the distribution of the possible outcomes of the index.

Market-Based Pricing

As in the equity market, market-based pricing consists of using the market price of the equity along with an appropriate model to derive the no-arbitrage price (see **Risk-Neutral Pricing: Importance and Relevance**). In the case of weather contracts, we could consider using the observable market price for the weather options as the value. But this will only be possible if there is an observable market.

At first sight, the payoff of a weather option depends on an index derived from meteorological variables, which is not a traded quantity, and as a result, dynamic hedging may not be possible. But if there is a swap contract defined on the index, then under certain assumptions, dynamic hedging of the risk in a weather option is still possible using swaps in the same way as equities is used to hedge equity options. See [1] for a no-arbitrage pricing method using weather swaps/forwards to hedge weather options. For such dynamic hedging to be possible, the underlying swap market has to be fairly liquid, otherwise the costs involved are huge. Another method along the same line was proposed in [2]. By assuming that the temperature follows a fractional Ornstein–Uhlenbeck process (see **Lévy Processes in Asset Pricing**), Benth [2] derived an arbitrage-free pricing formula for weather derivatives using the idea of quasi-conditional expectation.

Marginal Value Approach

Davis [3] valued weather derivative using the “shadow price” or the “marginal substitution value” approach from mathematical economics (see [4]). He modeled HDD and commodity prices by a geometric Brownian motion (see **Stochastic Control for**

Insurance Companies) and deduced expressions for option values and swap rates.

Equilibrium Valuation Approach

Cao and Wei [5] proposed to value weather derivative by means of the Lucas model. Lucas model is a consumption-based asset pricing model, where an economy consists of a large number of identical individual consumers. The Lucas model then relates the aggregate output of an economy to exogenous output variables (see [6]). Cao and Wei treated temperature as a fundamental uncertainty in the economy. After modeling the daily temperature by an autoregressive time series, they related it with aggregate dividends through correlations. They used this model to test the significance of market price of risk of temperature. Surprisingly, their empirical results showed that the market price of risk associated with temperature is insignificant. Their results also suggested that historical simulations will generally lead to overpricing of weather options.

Richards *et al.* [7] developed a general valuation method of weather derivatives based on the approach of Cao and Wei. They used a mean-reverting Brownian motion model with lognormal jumps and time-varying volatility to model the daily temperature. They concluded that the assumption of zero market price of risk is problematic when risk-neutral valuation principle cannot be applied. Further details about pricing of weather derivatives can be found in [8, 9].

In summary, weather option pricing is a mixture of actuarial and market-based techniques, with more emphasis on the actuarial side in most cases. For locations where the swap market is ill-liquid, actuarial valuation may be the only means. For locations where the swap market is sufficiently liquid, no-arbitrage pricing may have some relevance because dynamic

hedging using swaps may be possible. Finally, for locations where options are actively traded, one may be able to take the option valuation directly from the market.

Use of Weather Modeling in Pricing Weather Derivatives

Weather modeling cannot be separated from weather derivatives pricing. Weather forecast plays an indispensable role in weather derivatives market. Buyers need to evaluate as to how much weather risk is needed to be hedged in order to determine the correct number of weather contracts to enter. Sellers need to decide an appropriate price for weather derivatives. As price movements of traded contracts are usually driven by weather forecasts, a good weather forecasting model is instrumental in accurate pricing of weather contracts. Among different types of weather forecasting models, temperature forecasting is the most commonly studied one.

Modeling Temperature

Most weather forecasts are produced by dynamical models of the atmosphere known as *atmospheric general circulation models (ACGMs)*; see Section 9.1.3 of [8] and the references therein for further details about ACGMs. A lucid discussion on meteorology is given in [10]. Time series is another common approach used to model and forecast daily average temperatures. Figure 1 shows the daily average temperature time series from 1/1/2000 to 31/12/2004 for four US cities. All temperature data are obtained from the global summary of the day (GSOD) database archived by the National Climatic Data Center (NCDC).

Figure 1 Time series plots of daily temperature for four US cities

Global warming and solar activities may produce a deterministic trend for the temperature, though it is minor for this sampling period. The daily average temperature exhibits strong and stable seasonal trends in both mean and variance and oscillates regularly between high temperature (summer) and low temperature (winter) in a period of 1 year. Standard deviation also displays higher values in winter months but lower values in summer months. Each series has similar patterns although they are different in peak values across cities.

After removing the deterministic trends using standard methods as given in chapter one of [11], the remaining data is the anomaly. Unlike the cyclic trend observed in Figure 1, anomaly is the unpredictable component in temperature. In other words, it represents the temperature risk. Cabellero *et al.* [12] studied the behavior of anomaly and detected long-range dependence in Central England, Chicago, and Los Angeles. Moreno [13] introduced an ARFIMA-FIGARCH process to capture the long-memory and heteroskedasticity properties.

Another approach is to model the underlying index directly. But this requires an additional normality assumption for the distribution of the temperature index. Validity of the normality assumption was challenged in [14].

Weather Forecasting

As weather contracts usually last for months or seasons, weather models for pricing weather derivatives should provide good prediction power over an extended period of time. However, most of the meteorological weather forecasting literature only focuses at short-horizon forecasts using physical models. Meteorological models may not be the best means for weather contracts. Having a reasonable long-horizon weather forecast (or even a complete density forecast) is thus crucial for pricing weather derivatives.

To this end, Campbell and Diebold [15] estimated the unconditional distributions of daily temperature by using a nonparametric kernel density estimate. They accessed the performance of long-horizon density forecasts and obtained encouraging results. Another method of long-horizon weather forecasting is ensemble prediction. Ensemble prediction derives a more sophisticated density estimate for weather variables. The prediction systems

generate many realizations of weather variables using different initial conditions of numerical models. These are then used to construct an estimate of the density function (*see Copulas and Other Measures of Dependency*). Taylor and Buizza [16] compared the ensemble-based forecast with the univariate time series approach and concluded that the ensemble-based forecast outperformed the time series approach.

Conclusion

In this article, we present the history of the weather market, and discuss weather risks, weather derivatives, and their valuations. Since the weather derivative market is an incomplete market, traditional complete market pricing method may not be directly applicable. Further research is needed to develop an effective pricing method for incomplete markets of weather derivatives.

Hazards Insurance: A Brief History

Insurability Conditions

Multiattribute Modeling

NGAI H. CHAN AND CHUN Y. WONG

What are Hazardous Materials?

A hazardous substance is a material with a substantial potential to pose a danger to living organisms, materials, structures, or the environment. In a risk assessment context, this is called the *hazard identification phase*. Throughout history, humans have suffered from excessive exposure to hazardous substances. Exposure incidents range from inhalation of the noxious volcanic gases, death due to exposure to carbon monoxide from fires in caves, to lung diseases caused by using mineral asbestos fibers when weaving cloths in ancient Greece. Adverse health effects were observed in Europe during the 1700–1800s as a result of human exposure to hazardous material and toxicants in runoff from mine spoils piles and from poisoning due to exposure to coal tar by-product [1]. In the late 1900s, it became evident that environmental pollution and exposure to hazardous materials, particularly in industrialized countries, were becoming major problems (*see Environmental Hazard*).

According to Paracelsus, all chemicals and metals from synthetic to naturally occurring ones have the potential to be poisons, and only the dose differentiates a poison from a remedy. Depending on the dose, it is possible for any material to cause harm, no matter how benign or essential it is to life [2]. Recently, during fraternity hazing events, several college students drank excessive quantities of water and died owing to the resulting electrolyte imbalance.

Hazard is also described as an intrinsic capability of material to cause harm. The hazard posed by material can be a function of material toxicity, mobility, environmental persistence, bioaccumulation rate, and/or methods used to contain the material [3]. Hazards can be either natural (geophysical and biological) or technological (industrial emissions, accidents, and chemical spills). The technological hazards are those causing human injury, illness, or death, and ecological, environmental, and property damage (*see Environmental Hazard*). Hazard may also be associated with the toxicological, nuclear, chemical, or biological properties of a substance [4].

Legally, when a chemical is present in a consumer product or other media such as waste streams, the term *hazardous material* can have a specific meaning

and certain expectations may be imposed. Under most laws or regulations, a hazardous material is defined as an item or agent (biological, chemical, or physical) that has the potential to cause harm either by itself or through interaction with other factors [2]. Accordingly, any material, element, compound, or combination of materials that poses a threat to human health and the environment owing to its toxic, corrosive, ignitable, explosive, or chemically reactive nature is labeled a hazardous material [5–7].

Most regulatory programs have identified plans and procedures to evaluate quantitative estimate of risks associated with exposure to the hazardous material. The risk assessment program defined by the US National Academy of Sciences and the United States Environmental Protection Agency (USEPA) involves processes such as hazard identification, exposure assessment, toxicity assessment, and risk characterization [3, 8].

Regulatory Framework

Hazardous Material Characterization

Hazardous material is often measured and expressed in terms of its chemical properties. Accordingly, a fundamental knowledge of some basic concepts and principles of chemical basics are often needed in order to classify chemicals. Matters are generally divided into three physical states: solids, liquids, and gases. These terms, however, can take on a special significance when they are found in regulatory language [2].

Hazardous substances, a subset of hazardous materials, are identified and listed by regulatory agencies such as the USEPA and the Occupational Safety and Health Administration (OSHA) under various regulations. The main difference between the USEPA and OSHA is that OSHA is an enforcement organization and has major responsibility over safety and health issues in the workplace [7].

United States Environmental Protection Agency (USEPA)

Protection of the human health and the environment often requires development of regulatory frameworks and guidelines for proper characterization, prevention, handling, and management of hazardous material (*see Environmental Health Risk*). According

to the USEPA, hazardous materials encompass any material, including substances and wastes that may pose an unreasonable risk to health, safety, property, or the environment. In specific quantities and forms, these materials can often pose a danger of fire, become explosive, flammable, or undergo a reaction, which releases excessive heat. Regulatory citations are provided only for the statutes dealing most directly with pesticides and industrial chemicals [9, 10].

The USEPA further classifies hazardous materials as carcinogenic or toxic depending on the concentration, duration, and type of exposure, whether the material can cause sickness or death, and if exposure to those induces reactions in tissues causing cellular damage or death [3, 9]. For the purpose of quantifying human health risk, chemicals are characterized as carcinogens, which are those chemicals with demonstrated propensity for cancer induction, and noncarcinogens. If chemicals behave as both carcinogens and noncarcinogens, they appear in both types of calculations of potential human health risk assessments [3]. On the basis of tests conducted by the National Toxicology Program (NTP) of the National Institute of Environmental Health Sciences (NIEHS) and according to the weight of evidence from animal experiments, clinical experience, and epidemiologic studies, the USEPA also recommend the following classifications for chemicals: class A (human carcinogens), class B (probable human carcinogen), class C (possible human carcinogen), class D (not classified as human carcinogen), and class E (evidence of non-carcinogenicity for humans) [11].

Under some regulations, the USEPA also uses four criteria to list discarded material (waste) as hazardous: (a) the waste typically contains certain chemicals, and certain factors are considered, which decide whether it could pose a threat to human health and the environment in the absence of special regulation (toxic listed wastes); (b) the waste contains such dangerous chemicals that it could pose a threat to human health and the environment even when properly managed (acutely hazardous wastes); (c) the waste typically exhibits one of the four characteristics of hazardous waste described in the hazardous waste identification regulations (ignitability, corrosivity, reactivity, or toxicity); and (d) when EPA has a cause to believe, for some other reason, the waste typically fits within the statutory definition of hazardous waste developed by the US Congress [7, 12, 13].

The following sections present an overview of the four main criteria used in characterization of hazardous material by the USEPA regulations [13]. A comprehensive review of the regulations and the guidelines are found in the literature [9, 11–13].

Ignitability. Ignitable materials are wastes that can readily catch fire and sustain combustion. Most ignitable wastes are liquid in physical form. The USEPA selected a flash point test as the method for determining whether a liquid waste is ignitable and, therefore, can be classified as hazardous. The flash point test determines the lowest temperature at which a chemical ignites when exposed to flame ($<140^{\circ}\text{F}$). A nonliquid waste is ignitable and hazardous if it can spontaneously catch fire under normal handling conditions and can burn so vigorously that it creates a hazard. Certain compressed gases and chemicals called *oxidizers* can also be ignitable. The regulations describing the characteristics of ignitability are codified with the Code of Federal Register (CFR) (40 CFR part 261.21) [13].

Corrosivity. Materials with acidic or alkaline (basic) characteristics and capability of corroding steel at a rate greater than 6.35 mm yr^{-1} at a temperature of 55°C , or dissolving flesh, metal, or other materials (chemicals with pH between 2 and 12.5) are characterized as corrosive. The regulations describing the characteristic of corrosivity can be found in section 40 CFR part 261.22 [13].

Reactivity. A reactive material can readily explode or undergo violent reactions. Common examples are discarded munitions or explosives. In many cases, it is difficult to do tests for the material reactivity under normal conditions. Reactive materials undergo violent change without detonating, react violently with water, form explosive mixtures with water, and generate toxic gases, vapors, or fumes. Cyanide or sulfide-bearing materials (wastes) are considered reactive, since when present in solutions having a pH between 2 and 12.5 they generate gases, vapors, or fumes, and are capable of detonation or explosive reactions. The characteristic of reactivity is described in the regulations at 40 CFR part 261.23 [13].

Toxicity. Toxicity is another term commonly used in discussions of hazardous material. It refers to the

capacity to cause toxic effects in the living organisms, including human and ecological receptors [9]. The degree of toxicity varies with the particular chemical. Upon exposure, some chemicals can produce asphyxiation, causing oxygen concentrations in the blood to go below the level that is necessary to support life. Others, following ingestion, can damage vital organs such as liver or heart, and/or cause adverse effects on the nerves and ability of the nerves to transfer impulses [6, 14].

Toxicity is often characterized as chronic or acute. Chronic toxicity is the occurrence of symptoms, diseases, or other adverse health effects that develop or persist over time following exposure to a single dose or multiple doses of a chemical over a long period of time. Acute toxicity is the development of symptoms of poisoning or the occurrence of adverse health effects after exposure to a single dose or multiple doses of a chemical within a short period of time. The risk is the statistical probability that a toxic response will be observed [2].

USEPA suggested a toxicity characteristic leachate procedure (TCLP) for determination of the toxicity level of the material containing hazardous chemicals. A substance is determined to be toxic if the results of TCLP tests indicate that it contains chemicals with concentrations exceeding published levels of contaminants listed in 40 CFR 261.24. Examples of toxic material listed by the USEPA include arsenic, barium, cadmium, chromium, lead, mercury, selenium, silver, endrin, lindane, methoxychlor, and toxaphene [12, 13].

Occupational Safety and Health Administration (OSHA)

OSHA defines hazardous materials and chemicals in terms of the “health hazards” and “physical hazards”.

Health hazards include chemicals that are carcinogens, toxic agents, irritants, corrosives, and sensitizers; agents that act on the hematopoietic system; agents that damage the lungs, skin, eyes, or mucous membranes; chemicals that are combustible, explosive, flammable, oxidizers, pyrophorics, unstable-reactive, or water-reactive; chemicals that, in the course of normal handling, use, or storage may produce or release dusts, gases, fumes, vapors, mists, or smoke, which may have any of the previously mentioned characteristics (29 CFR 1910.1200) [5, 12]. Physical hazards are an entirely separate

category under OSHA. These include heat stress, exposure to nonionizing and ionizing radiation, vibration, excessive or inadequate lighting, ergonomic stresses, and others.

Hazard Impact Analysis and Toxicity

Quantitative measures of hazard consequences of hazardous material can be determined in terms of risk, which are conditional probabilities of experiencing harm, its likelihoods, and severity of the harm. Hazard impact analysis is a science-based estimate of the human health risk due to exposure to hazardous material. Risk assessment can estimate the probability that a particular substance will pose a certain adverse effect to humans and the environment. Risk is estimated as a range of probabilities and characterized by both uncertainty within the data and assumptions made during the assessment processes. Risk starts with the exposure, which is defined as the contact of an organism’s exterior with a chemical.

Toxicologically, exposure is the means by which the living organism acquires a dose, which is defined as the total amount of chemicals received through contact with various substances (i.e. toxic material). Exposure can be categorized as external and/or internal. External exposure is linked closely to the chemical’s environmental dissipation, contact rate, the quantity of the chemical available, and the time. The internal exposure, however, is the amount of the chemical absorbed into the systemic circulation [14].

The USEPA recommends a four-step procedure for assessing human health risk. The procedure consists of (a) hazard identification, (b) dose–response assessment, (c) exposure assessment, and (d) risk characterization [8]. Hazard identification demonstrates whether exposure to an agent can cause or increase a particular adverse health effect [15]. The process involves gathering and evaluating data on the types and extent of the consequences produced by hazardous situations or substances. Toxicity assessment emphasizes establishment of dose–response characteristics, a graphical representation of the relationship between the degree of exposure to a chemical substance, and the hazard predicted by the biological effects or responses [15].

When the extent of any particular response is plotted against dose (exposure level), a characteristic

Figure 1 Illustration of dose–response curves, LD₅₀, and LD₉₀, identified for two different chemicals used in a toxicological study

S-shaped curve is produced. As shown in Figure 1, the response of the test organism (identified as percent effect) varies according to the magnitude of the administered dose and the potency of the material used in the study. The LD₅₀ and LD₉₀ represent lethal dose affecting 50 and 90% of the test population, respectively. In cases where the observed response is death, the dose–response curve (*see Dose–Response Analysis*) can be used to estimate the LD₅₀ (the dose that will kill about 50% of the animals). Similarly, depending on the classification scheme that is used, a nonlethal response may be quantified as an effective dose (ED) or a toxic dose (TD) [14].

The highest dose for which no response is observed is identified as the no observed effect level (NOEL), while the lowest dose to give the response may be termed the *toxic threshold*, again, depending on the regulatory or classification system used. Some chemicals, like the genotoxic carcinogens, can be assumed to have no threshold dose for regulatory purposes [15].

Dose–response curves can also be used to identify toxicological criteria such as lowest observed adverse effect level (LOAEL), lowest observed effect level (LOEL), and no observed adverse effect level (NOAEL) in units of milligram per kilogram of body weight per day. The slope factor (SF) can also be determined from the dose–response curve. On the basis of regulatory convention, the SF is the plausible upper-bound estimate (estimate not likely to be

lower than the true value) of the probability of an individual developing cancer as a result of a lifetime of exposure to a particular level of a potential carcinogen [2, 15].

The dose–response estimation process takes into account the uncertainty within the process, defined as the lack of confidence in the estimate of a variable’s magnitude or probability of its occurrence. Factors such as genetic fitness, metabolic differences, body fat, the level and extent of antagonism, bioaccumulation, and bioconcentration of chemicals in body and cell tissues control experimental outcome for the administered doses [11]. Hypersensitive organisms respond at a low dose end and resistant organisms at the other. If the test population were homogeneous, the dose–response line would be essentially vertical. The steepness of the slope helps to determine the degree of homogeneity of the population tested [14].

Hazardous Material Management

Mitigating the risk associated with exposure to hazardous materials requires the application of safety precautions during their production, handling, transportation, storage, use, and disposal. Most countries have recognized the need for regulating hazardous material. In the United States, proper management of hazardous materials has been defined through numerous administrative requirements. These have

been identified through regulations promulgated by various agencies such as USEPA, Nuclear Regulatory Commissions (NRC), National Institute for Occupational Safety and Health (NIOSH), Department of Transportation (DOT), and several acts such as Toxic Substances and Control Act (TSCA), Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), Federal Food, Drug, and Cosmetic Act (FFDCA), Emergency Planning, and Community Right-to-Know Act (EPCRA) (mandates a national inventory of toxic chemical releases (Toxics Release Inventory (TRI)), Clean Air Act (CAA), Clean Water Act (CWA), Safe Drinking Water Act (SDWA), Resource Conservation and Recovery Act (RCRA), Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), Hazardous Materials Transportation Act (HMTA), Federal Hazardous Substances Act (FHSA), Consumer Product Safety Act (CPSA), Poison Prevention Packaging Act (PPPA), and Occupational Safety and Health Administration [10].

The exposure mitigation methods include the use of material safety data sheet, promulgation of exposure limits, testing for toxicity characteristics to medical surveillance programs, and dozens of other miscellaneous administrative and engineering control initiatives [2, 5, 12, 13]. In order to assist hazardous material management programs nationwide, a list of hazardous material is published by numerous governmental, trade, and professional agencies. Those include but are not limited to (a) 189 hazardous air pollutants in Title III of CAA amendments, (b) Registry of Toxic Effects of Chemical Substances (RTECS) (NIOSH), (c) list of toxic and hazardous substances (OSHA), (d) Pocket Guide to Chemical Hazards (NIOSH), and (e) Threshold Limit Values for Chemical Substances and Physical Agents in the Workroom Environment with Intended Change (published and updated yearly, American conference of governmental and industrial hygienists (ACGIH)) [16].

Zero Failure Data

This article considers estimation of the reliability of a “system” when no failures have been observed (*see Reliability Demonstration*). The term *system* refers to the hardware under consideration, which may be as simple as a fuse or as complex as an entire nuclear power plant. The “zero-failure-data” case is not the same as the “no-data” problem. In other words, we assume here that the system has been observed for some time T (or demanded N times) but that no failures have been observed. In the no-data situation, the system would never have been observed.

Estimating risk when no failures have been observed is inherently extremely difficult. Unfortunately, the situation is also quite common: any time a first of a kind prototype system or plant is built, the risk prediction is based on no data, and even after operation starts there is a period of zero failures for many components. Yet failure rates or failure probabilities need to be estimated.

Several approaches are possible.

- Be content with a “pessimistic” estimate, an upper bound only.
- Find data for similar equipment, and construct an estimate with the aid of the other data.
- Analyze the parts, ways, or processes by which the system can fail, and use data on these various parts to construct an estimate for the system as a whole.

These three topics form the main sections of this article. A final section discusses the situation when few failures, rather than no failures, are observed.

Pessimistic Estimates

The zero failure data give no information on how small the risk might be. They only give information on how large the risk might be. In other words, the observed absence of failures enables one essentially to rule out very large values of the failure probability or failure rate. Formally, various upper bounds – confidence upper bounds or upper percentiles of Bayesian distributions can be constructed (*see Imprecise Reliability; Lifetime Models and*

Risk Assessment; Mathematics of Risk and Reliability: A Select History; Meta-Analysis in Nonclinical Risk Assessment). However, any small value of the probability of failure or failure rate, no matter how small, is in principle consistent with the observed lack of failures.

Basic Pessimistic Upper Bound and Point Estimate

The upper limit can be defined formally in several equivalent ways: as the smallest value that would be rejected by a hypothesis test, or as a confidence limit, or as the upper end of a Bayes credible interval based on some suitably pessimistic prior. Formulas are simple in two common cases given here.

1. Suppose first that the failures occur according to a Poisson process, or equivalently, the times between failures are independent and exponentially distributed, with failure rate λ . The probability of zero failures in time T is $e^{-\lambda T}$. A hypothesis test would reject a λ value at the significance level 0.05 if this probability is ≤ 0.05 , that is, if $\lambda \geq -\ln(0.05)/T$. Alternatively, a 95% confidence upper bound based on x failures in time T is $\chi^2_{0.95}(2x+2)/2T$ [1], where $\chi^2_{0.95}(df)$ denotes the 95th percentile of a χ^2 distribution with df degrees of freedom. This can also be expressed as $\text{gamma}_{0.95}(x+1, T)$, the 95th percentile of a gamma distribution. Therefore, the 95% confidence upper bound based on zero failures in time T is $\text{gamma}_{0.95}(1, T)$. All these formulas can be shown to give the same numerical limit, $3.00/T$. The upper limit can be found similarly for other significance levels/confidence levels, simply by changing 0.05 and 0.95 to the desired values.

A Bayesian distribution that corresponds exactly to this upper limit for all confidence levels is found as follows (*see also Bayesian Statistics in Quantitative Risk Assessment*). The conjugate prior for λ is $\text{gamma}(\alpha_{\text{prior}}, \beta_{\text{prior}})$, and the posterior distribution based on zero failures in time T is $\text{gamma}(\alpha_{\text{prior}} + 0, \beta_{\text{prior}} + T)$ [2]. Therefore, the prior distribution that yields posterior percentiles that match confidence limits of the above form is uniform [formally, $\text{gamma}(1, 0)$]. The resulting posterior 95th percentile is $\text{gamma}_{0.95}(1, T)$, agreeing exactly with

the above 95% confidence limit, and all the limits for other confidence levels also agree. The mean of this distribution is $1/T$, a value that we might choose as a point estimate.

Another way to think of conservative estimation is as follows: base the decision on the exponentially distributed times to failure. When you observe no failures up to time T , the most conservative assumption imaginable, still consistent with the observation, is to assume that the first failure would occur at the next moment $T+$. The resulting confidence bound is conservative, and happens to be exactly the same as the upper confidence limit given above for the Poisson model [3].

2. On the other hand, failures may occur on demand. The binomial model assumes that failures on distinct demands are independent, and that the probability of failure on any demand is some number, denoted q . The probability of zero failures in N demands is $(1 - q)^N$. A hypothesis test would reject a value of q at the 0.05 significance level if this probability is less than 0.05, or equivalently if $q \geq 1 - 0.05^{1/N}$. Alternatively, the classical 95% confidence upper bound for q , based on x failures in N demands, is the 95th percentile of a $\text{beta}(x + 1, N)$ distribution [1]. Therefore, the 95% confidence upper bound based on zero failures is $\text{beta}_{0.95}(1, N)$. These two approaches can be shown to give the same numerical limit. The limit for significance levels other than 0.05 can be found in the same way.

A Bayesian distribution that corresponds exactly to these upper limits for all confidence levels is easily found. The conjugate prior for q is $\text{beta}(\alpha_{\text{prior}}, \beta_{\text{prior}})$, and the posterior distribution based on zero failures in N demands is $\text{beta}(\alpha_{\text{prior}} + 0, \beta_{\text{prior}} + N - 0)$ [2]. Therefore, the prior distribution that yields posterior percentiles matching the upper confidence limits given above is $\text{beta}(1, 0)$. The resulting posterior 95th percentile is $\text{beta}_{0.95}(1, N)$, which agrees with the 95% confidence limit found above.

The mean of this distribution is $1/(N + 1)$, an estimate that we might use if we assume that the first failure will occur on the very next demand after the N observed demands. This is a pessimistic assumption that may be used in point-value risk assessments.

These bounds and distributions are based on the question, “How large could the parameter be, and how confident can I be about it according to the data alone?” The procedure does not use any external information that might indicate that the parameter actually is substantially smaller than the conservative distributions suggest.

When the observation period is small – a short observation time or a few demands – the conservative upper bound can be unrealistically large, and unacceptable as an estimate. But there are cases when the upper bound is acceptable, especially for components that are not so important to risk.

Less Pessimistic Estimates

If one or more failures are present, we can obtain both upper and lower confidence limits. There is no Bayes prior distribution whose posterior distribution matches both the lower and upper confidence limits for discrete Poisson or binomial observables, but a compromise is the “Jeffreys noninformative prior”, $\text{gamma}(0.5, 0)$ for failures in time and $\text{beta}(0.5, 0.5)$ for failures on demand [2–4] (*see also Bayesian Statistics in Quantitative Risk Assessment*). The $\text{gamma}(0.5, 0)$ distribution is an example of an “improper” distribution, having a density with an infinite integral; however, if it is manipulated formally, the resulting posterior distribution is proper. Therefore, improper priors are allowed (and regarded, if necessary, as limiting approximations of proper distributions).

On the basis of x failures observed in time T or in N demands, the posterior distribution is $\text{gamma}(x + 0.5, T)$ or $\text{beta}(x + 0.5, N - x + 0.5)$. Heuristically, these results correspond to assuming an extra half failure. Depending on the viewpoint, this half failure may be imagined as occurring just after time T or demand N , or prior to the data, in zero time or on one prior demand. The results are less pessimistic than with the priors given above in the section titled “Basic Pessimistic Upper Bound and Point Estimate”.

Consider first the Jeffreys prior for failures in time. If zero failures are observed in time T , the posterior distribution for the failure rate λ is $\text{gamma}(0.5, T)$. The posterior mean is $1/(2T)$, half the pessimistic mean. The 95th percentile is 0.64 times the 95th percentile when the most pessimistic prior is used. With the Jeffreys prior for failures on demand, the posterior mean is $1/(2N + 1)$, approximately half the

pessimistic mean. The 95th percentile is smaller by a factor 0.81 than the 95th percentile when the most pessimistic prior is used and when $N = 1$, and by a factor 0.64 when N is large.

Another way to the above conclusions is as follows. In case of at least some failures ($x > 0$), it is also possible to estimate the failure rate using *failure truncated* data (see **Reliability Growth Testing; Repairable Systems Reliability**), in which case the observable is the time to the x th failure, T_x , a continuous variable. This has an Erlang (or Erlangian) distribution $\text{gamma}(x, \lambda)$, and all confidence bounds for λ are given by the distribution $\text{gamma}(x, T_x)$, or equivalently $\chi^2(2x)/(2T_x)$. The prior density that yields this as a posterior in the Bayesian process is $\text{gamma}(0, 0)$, the inverse of the failure rate. Instead, when the observations are *time truncated* at some fixed T , with x failures observed, one can say for sure that T is longer than the time to the x th failure and shorter than the time to the $(x + 1)$ th failure. As a heuristic compromise, T is formally the observed time to the $(x + 1/2)$ th failure. This yields confidence bounds based on $\chi^2(2x + 1)/(2T)$, consistent with the Jeffreys prior for Poisson data, $\text{gamma}(0.5, 0)$ [3].

Estimates Based on Data from Similar Equipment

When failure data are available on similar components under reasonably similar conditions, the methodology depends strongly on the degree of similarity, and on the detail of the data. If data can be assumed to be from identical systems and conditions as the system of interest, one may pool the numbers of failures and observation times (or numbers of trials) and use well-known formulas to estimate λ or q . This highest degree of similarity is rarely the case. The next two subsections consider two cases with equipment that is similar to, but not identical to, the equipment of interest.

Detailed Data from Similar Systems

Suppose that it is possible to find failure data on a family of equipment whose members are not identical but are “similar enough” to the equipment of interest, in the sense that one can consider the latter as a sample from the same family. For example, steam generators used at WWER (water-cooled

water-moderated energetic reactor) nuclear power plants are quite similar, but maintenance practices and water chemistry vary among the plants, causing variation in tube rupture frequencies. It is reasonable to assume each plant to be a sample from the same family. This allows use of empirically based Bayesian methods, with either “empirical Bayes” (see **Repairable Systems Reliability; Common Cause Failure Modeling; Cross-Species Extrapolation**) or “hierarchical Bayes” implementation (see **Bayesian Statistics in Quantitative Risk Assessment**) [3, 5]. This approach can be used in estimating tube rupture frequencies for each plant, including the plant of interest. It satisfies those who want to use available data to the maximal extent possible. This procedure also yields proper values for plants that have themselves experienced no failures or even have no data at all.

Of course, there is subjectivity in judging which units form a family of “similar enough” units to form a sampling/prior distribution. But there are ways to experiment with alternative families to sort this out. For example, one can try failure data from *all* pressurized water reactor steam generators and see how the family distribution differs from that obtained for WWER units alone. Presumably, the latter is narrower because the units are the same type and more similar. Consequently, the posterior for the unit of interest is more accurate. In any case, even a wider sampling/prior distribution is usually better than any noninformative prior distribution.

Even in the empirical Bayes or hierarchical Bayes cases, the lower bounds cannot necessarily be estimated accurately. The values can depend strongly on the assumed model. An example is given in [5] of failure to start, with 68 plants, hundreds of demands, and only six failures. The problem is to estimate q , the probability of failure to start, at each plant. Two hierarchical Bayes analyses (see **Common Cause Failure Modeling; Meta-Analysis in Nonclinical Risk Assessment**) are performed, one assuming that q follows a beta distribution between plants and the other assuming that q follows a logistic-normal distribution. For plants with zero failures, the 95th percentiles agree for the two models to within a factor of 2, and the means agree within a factor of 3. The fifth percentiles, on the other hand, disagree by over 10 orders of magnitude. Similar behavior can be noticed in other comparisons [6].

For additional real applications of these methods in risk assessment, the reader is referred to [6–9].

Summary Data from Similar Systems

Sometimes, failure data or rate estimates for certain component types are available from various branches of industries, even if not exactly for the plant or industry under investigation. Such data also may be available in summary form, such as a value from a handbook. This kind of generic data may be too scattered and diverse for formal manipulation. “Engineering judgment” has been used for years to obtain meaningful central estimates and uncertainty bounds, accounting for similarities and differences of systems and operating conditions.

One less subjective way would be to use a so-called constrained noninformative prior [10]. This is a prior distribution that maximizes the entropy (in a suitable parameterization) subject to the constraint that the mean equals a known value. It is a generalization of the Jeffreys prior, adding the constraint of the mean. For highly reliable equipment, the Jeffreys prior is typically overly pessimistic, and the constrained noninformative prior seems to be inherently more realistic, at least with respect to the mean. This prior can then be updated using the data from the system of interest.

Analysis and Synthesis of the Failure Processes

A final method used for systems with no observed failures is to analyze the ways that failure can occur, possibly decompose the system into more primitive pieces, and use available data on these processes or contributors to construct an estimate for the system. Several of the many applications of this method are pointed out here.

A notable success in this regard is probabilistic safety assessment (PSA) in the nuclear power industry. The methodology is also known as *probabilistic risk assessment* (PRA) (see **Probabilistic Risk Assessment**). The first well-known major study in the United States [11] was completed in 1975. That study was largely based on generic failure probability estimates for components such as pumps, valves, diesel generators, etc. based on median estimates of the type described in the section titled “Summary

Data from Similar Systems”, and similarly for the rates of initiating events like pipe breaks and loss of electric power. Uncertainty studies were performed by propagating the uncertainty distributions of the input parameters through the model.

Since then, most commercial plants have performed wide-scope risk studies and established extensive failure and maintenance data collection systems. Consequently, the methodologies of the section titled “Detailed Data from Similar Systems” can be widely used. Although zero core-damage accidents have occurred in plants with modern design and upgraded safety features, the accident frequency can be estimated with ever-increasing accuracy.

Analysis of the processes contributing to failure is also the basis of load-strength interference. For example, practically all external event PSAs (seismic, extreme winds, snowstorms, seaweeds, floods, etc.) consider events that have never happened (at the site under study). The observed intensities (loads) of these events need to be extrapolated to such values that they could cause failures. The strength measures (or fragilities) also have distributions that need to be estimated. Convolution integrals of the loads and strengths then yield failure probabilities for components and structures [12].

Similarly, very large pipe breaks have never occurred in commercial nuclear reactors. However, degradation may be based on mechanistic structural failure phenomena (fatigue, wear, stress-corrosion cracking, flow-induced thinning, etc.), which in turn are based on material properties and system characteristics (flow, pressure, temperature, coolant chemistry, etc.). Interference with strength characteristics then yields failure probabilities [13].

Comparison of “Few” Failures with No Failures

If a few failures have been observed, rather than none, some of the above discussion remains essentially unchanged:

- Experience from outside the system may still be very useful in estimating risk, using the Bayesian approach. In particular, the methods given above in the section titled “Estimates Based on Data from Similar Equipment” are still useful.
- Decomposing the system into more primitive pieces, with data available for each piece, may

also be useful, as in the section titled “Analysis and Synthesis of the Failure Processes”.

In other respects, however, having at least one observed failure is much more useful than having none:

- We no longer need to be content with an upper bound only.
- A Bayesian conclusion is less sensitive to details of the prior. If a conjugate gamma or beta distribution is used, and x failures are observed, the posterior first parameter is $(\alpha_{\text{prior}} + x)$. This posterior distribution is much less dependent on α_{prior} for $x \geq 1$ than for $x = 0$. As an example of the latter, [14] assumes that zero failures occur in some testing period, and this leads to a struggle with the sensitivity of the prediction results to the value of α_{prior} .
- The sensitivity to the prior is further magnified when the prior is used repeatedly in an analysis, for example, when several failure modes are considered in a single analysis.
